Abbreviations and definitions

Environmental Decision	Decision on environmental conditions issued by the Regional Director for Environmental Protection in Gdansk on July 7, 2016, mark: RDOŚ-Gd-WOO.4211.12.2015.KP.22, for the project entitled. "Construction of the Bałtyk III Offshore Wind Farm"
DWA	Decision on environmental conditions for the project
KPA	Act of June 14, 1960 Administrative Procedure Code (i.e. OJ. U. of 2021, item 735, as amended).
IMF BII	Bałtyk II Offshore Wind Farm
OWF BIII/ Project	Bałtyk Środkowy III Offshore Wind Farm
NIS 2015	The worst case scenario from the Report 2015, which is a set of project parameters causing the worst case impacts, and which was the basis for conducting the environmental impact assessment during the procedure concluded with the issuance of the Environmental Decision.
EIA	Environmental impact assessment
PSZW	Permit for the erection and use of artificial islands, structures and devices in Polish maritime areas
Report 2015	Environmental impact assessment report for the proceedings completed by the decision of RDOŚ dated July 7, 2016, mark: RDOS-Gd-WOO.4211.12.2015.KP.22
Report/EIA Report	Report on environmental impact for the amendment of the environmental decision issued for the Bałtyk Środkowy III OWF
RDEP	Regional Director of Environmental Protection in Gdansk
EIA Act	Act of October 3, 2008 on access to information on the environment and its protection, public participation in environmental protection and on environmental impact assessments (Journal of Laws of 2020, item 283, as amended).

1. Subject matter of the report and justification for proceeding.

The subject of this EIA Report is the environmental impact assessment of the project involving the construction of the offshore wind farm OWF Bałtyk Środkowy III ("OWF BIII", "the Project"), which has already received the decision on environmental conditions issued by the Regional Director for Environmental Protection in Gdańsk on July 7, 2016, mark: RDOŚ-Gd-WOO.4211.12.2015.KP.22 (the "Environmental Decision"). The report was prepared and submitted in the course of proceedings to amend the decision on environmental conditions, based on the provision of Article 87 of the Act of October 3, 2008 on the provision of information on the environment and its protection, public participation in environmental protection and environmental impact assessments (ie. Journal of Laws 2022, item 1029; "EIA Act") in connection with the provision of Article 155 of the Act of June 14, 1960 Code of Administrative Procedure (i.e. OJ. U. of 2021, item 735, as amended; "KPA"). In this case, the provisions on the environmental decision shall apply accordingly. The nature of the proceedings in question, i.e. amending an existing decision rather than obtaining a new environmental decision, has a major impact on the shape and content of this report.

The basic assumptions of the OWF Bałtyk Środkowy III project have not changed. However, since the issuance of the Environmental Decision, significant technological progress has been observed with regard to installations used for offshore wind farms, as a result of which solutions are available that were not foreseeable at the stage of obtaining the aforementioned decision, and which make it possible to achieve the same result in terms of energy generation with reduced environmental impacts, and the Project itself is at a much more advanced stage of development. It should also not be overlooked that since the issuance of the Environmental Decision, enormous progress has been made in the knowledge of natural resources in Polish marine areas, of other investments of this type planned in the vicinity of the Project. Thanks to further studies of the marine environment and analyses of the impact assessments of successive offshore wind farms, knowledge of the impacts caused by the construction and operation of such projects has been significantly enriched. The consequence of the development of other offshore wind farm projects is a significant change in the factual conditions, including as a consequence of the obligations imposed in the content of the issued decisions on environmental conditions, and which constitute the implementation environment of the OWF Bałtyk Środkowy III. In the issued decisions on environmental conditions, the environmental protection authorities determined the shape and location of corridors ensuring undisturbed migration of birds to Slupsk Shoal, validated a significant part of the statements on the potential impacts of other offshore wind farm projects planned in Polish maritime areas, including the cumulative impacts of these projects and the Project, and verified a number of solutions for the proposed minimization measures.

Regardless of the environment in which the Project is being prepared, it is particularly important to emphasize the development work on the OWF Bałtyk Środkowy III project itself, which has been going on since the date of issuance of the Environmental Decision, i.e. since July 2016. Since then, wind measurements have been carried out, preliminary geotechnical studies have been performed, and the boundary conditions defined by the Environmental Decision have been used to prepare a plan for the deployment of the farm's infrastructure and preliminary verification of possible technologies to be used. Changes in the scope of equipment and installations used for the implementation of the farm were also influenced by technological advances, which, on the one hand, make it possible to reach for solutions that were unavailable at the time of obtaining the Environmental Decision, and, on the other hand, cause than some solutions are being phased out and will not be available at the time of implementation

OWF Bałtyk Środkowy III. All of the above factors influenced the decision to update the environmental impact assessment of the OWF Bałtyk Środkowy III, so as to consequently adjust the content of the held Environmental Decision to the current technical and organizational assumptions of the project, at an advanced stage of development, and also influenced by technological changes. In addition, since the issuance of the decision, there has been a change in the implementation environment of the OWF Bałtyk Środkowy III project, an update in knowledge of the marine environment and the impacts associated with the construction and operation of offshore wind farms cumulative impacts with the Project. This is because the Applicant is convinced that both the stage of preparation for the implementation of wind energy in Polish maritime areas, as well as the stage of advancement of the OWF Bałtyk Środkowy III project, allow already at this stage to effectively verify the parameters of the planned project and some of the conditions imposed by the Environmental Decision.

The provision of Article 155 of the KPA, which is applicable to the case at hand, allows a final decision, by virtue of which a party has acquired rights, to be amended at any time with the consent of the party, if a special provision does not oppose such an amendment and the public interest or the legitimate interest of the party supports it. It should be emphasized that in the present case, the justification for changing the decision is both the legitimate interest of the Party and the public interest. Conducting this proceeding will make it possible to adjust the technical parameters of the OWF Bałtyk Środkowy III Project and the conditions for its implementation to the best offshore wind farm technologies planned for implementation and the best practices for conducting construction works. The changes to be made will allow the project to adapt to technological developments and optimize the solutions adopted in such a way that they will allow the Project to be more efficient without increasing environmental impacts. Such an action is fully in line with the public interest related to the need to urgently provide new generating capacity in the Polish power system, reduce the dependence of the Polish energy sector on external suppliers, and strive to achieve climate neutrality by increasing the share of renewable sources in Poland's total energy mix and the resulting reduction in greenhouse gas emissions.

The subject of the proposal is also to modify the conditions imposed by the Environmental Decision, including the condition related to the need to conduct a re-evaluation of the environmental impact in the course of the construction permit. This action will optimize the process of implementation of the Project significantly shortening the stage of its preparation for implementation and operation, while respecting the natural and social environment and in accordance with the principles of sustainable development.

Optimization and acceleration of the process of preparation of the implementation of the OWF Bałtyk Środkowy III project is also clearly a legitimate interest of the Party. Shortening the overall process allows the project to be more cost-effective and allows the project to enter the operation phase of the project more quickly by reducing the period during which the project does not allow the project to generate a profit, but causes costs. At the same time, it should be emphasized that the proposed amendment to the Environmental Decision is not opposed by any legal provision, nor does the amendment itself lead to a violation of the public interest. The social interest that the decision on environmental conditions realizes is expressed in the assessment of the possibility of realization of the planned project in a given location and such determination of the conditions for its implementation as to minimize the possibility of negative effects on people and the environment associated with the implementation and operation of the Project. The proposed change to the terms of the Environmental Decision does not in any way lead to a reduction in the level of protection of people and the

environment established by the existing content of the decision - as demonstrated in the body of the Report. This change is possible precisely as a result of updating and clarifying the parameters of the Project, including in connection with taking into account already at this stage some of the recommendations and conditions set forth in the Environmental Decision, as well as technological advances that allow optimizing the use of resources. Also of significance are the changes in the factual situation caused by the issuance of environmental decisions for other offshore wind farm projects and the knowledge of the natural resources of Polish marine areas and the impacts caused by offshore wind farms, obtained through the proceedings concluded by these decisions.

And, in particular, it should be pointed out that the impact assessment carried out in this Report has a dimension and effect equivalent to the environmental reassessment, and thus the purpose of imposing the reassessment as specified in the text of the Environmental Decision will be achieved.

2. Requested change in the parameters of the Project and the conditions of the Environmental Decision

The proposed change in the parameters of the Project is in the nature of an adjustment to the current state of knowledge and best available technology of the parameters, which in the Environmental Decision in most cases were specified as acceptable maximum parameters. In many cases, the Environmental Decision allows the investor to choose from among the methods of implementation of the Project evaluated in the course of the environmental impact assessment, as well as from among a group of specified technical solutions. Proposed changes to the parameters of the Project will either lead to a reduction in the maximum total range of conditions specified in the Environmental Decision or to a reduction in the range of project implementation methods or technical solutions. Changes in the parameters of the Project that exceed the parameters specified in the Environmental Decision - the maximum height of the rotor and the maximum diameter of the rotor, as well as the maximum area of the foundation for the associated infrastructure - are at the same time combined with radical changes in the number of power plants planned for implementation, as a result, the changes made in the number of power plants not only compensate for the changes in the impacts associated with changes in these parameters, but lead to a significant reduction. The table below summarizes the basic parameters of the Project subject to updating compared to the parameters approved by the Environmental Decision and to the most far-reaching scenario (NIS 2015), which is a set of parameters of the Project causing the most far-reaching impacts, and which was the basis for conducting the environmental impact assessment during the proceedings concluded with the issuance of the Environmental Decision.

Table 1. Comparison of basic parameters of the Project subject to change and clarification

	Parameters of the Project at the current stage of project development	Parameters of the Project approved in the Environmental Decision	Parameters constituting the 2015 NIS that form the basis of the impact assessment for the Project approved by the Environmental Decision*
Maximum number of power plants [pcs]	60	120	200

Maximum total height of the power plant above sea level. [m]	310	275	212.5
Maximum rotor diameter [m]	250	200	192.5
Maximum total rotor area [m2]	2945244	3768000	5820800
Minimum clearance between the bottom position of the wing and the sea surface [m]	20	20	20
Maximum number of foundations of supporting infrastructure** [pcs]	1	6	8
Maximum bottom area occupied by 1 foundation of supporting infrastructure [m^2]	1964	1257	1257
Types of power plant foundations considered	Foundations: monopile and jacket (truss) type	Foundations: monopile, tripod, jacket (truss) and gravity foundations	Foundations: monopile, tripod, jacket (truss) and gravity foundations
Maximum bottom area occupied by 1 power plant foundation [m^2]	79	1257	1257
Maximum bottom area occupied by all foundations [m^2]	6676	158382	261456

*The 2015 NIS is a set of parameters of the Project that cause the most far-reaching impacts, and which was the basis for conducting the environmental impact assessment during the proceedings that ended with the issuance of the Environmental Decision, for most of the parameters of the Project, the parameters of the NIS corresponded to those of the alternative variant from the 2015 Report

** The types of foundations considered have not changed.

The above table indicates those of the basic parameters of the project that were changed and clarified during the design work, detailed information is provided in Section 1 and Section 2 of Volume II of this Report.

The proposed update to the parameters of the Project also applies to exemptions from development within the Project basin. Thus, as a result of planning work on the project and in the execution of condition IV.1 of the Environmental Decision, i.e. in the analysis of potential safety zones for birds and bats in the area of the farm and around its individual elements, and condition IV.2 of the Environmental Decision related to the determination of the legitimacy of the creation of migration corridors Of the Environmental Decision related to the determination of the legitimacy of the creation of migration corridors, as well as taking into account the decisions contained in the decision on environmental

conditions issued for the offshore wind farm Balitca 2 and Baltica 3[1] a decision was made to exclude part of the BIII offshore wind farm area from the development of wind power plants, for the purpose of creating an expensive migration corridor for birds between clusters of wind power plants, belonging to projects located on the northern and north-eastern slope of Slupsk Shoal - detailed information in this regard can be found in Section 1 of Volume II and Section 5 of Volume IV. The extent of the protection zone resulting from the need to protect the shipwreck located in the project area, as stipulated in Condition I.3.9 of the Environmental Decision, has also been taken into account - detailed information in this regard can be found in Section 1 of Volume II and Section 8 of Volume IV.

Changes and updates to the parameters of the Project, made taking into account the recommendations set forth in the Environmental Decision, combined with the change in factual conditions resulting from new knowledge on the impacts of offshore wind farms, the degree of advancement of other offshore wind farm projects, including those cumulating impacts with the Project, as well as the advancement of the OWF Bałtyk Środkowy III project itself and technological progress, allows to indicate those conditions of the Environmental Decision that should be verified and amended, which is the scope of the subject application of the Investor.

The scope of the proposed changes to the terms of the Environmental Decision includes, in particular:

1. The change specified in I.1. Environmental Decision of the area to be developed in accordance with the conditions set forth in the PSZW from about 89 square kilometers to about 94 square kilometers. This change is due to the improper definition, inconsistent with the regulations of the Law of July 7, 1994. - Construction Law (i.e. Journal of Laws 2021, item 2351, as amended) above the area indicated in the application for the Environmental Decision and the 2015 Report. These changes do not lead to an actual enlargement of the area designated for this type of activity, and are only a consequence of adjusting the conceptual apparatus to that used in the Construction Law, as well as removing potential inconsistencies with condition I.3.8 of the Environmental Decision. In detail, this issue is presented in Section I of Volume 2;
2. The change in point. I.1. The Environmental Decision parameters of the offshore wind farm OWF Bałtyk Środkowy III by indicating that it will consist of a maximum of 60 wind turbines instead of 120 and a maximum of 1 internal offshore substation instead of 6;
3. Modification of the specified in Section I.1. The Environmental Decision parameters of the maximum total height of the power plant above sea level from 275 m to 310 m and the maximum rotor diameter from 200 m to 250 m, while changing the maximum zone of a single rotor from 31,400 m^2 to 49,088 m^2 and determining the maximum total zone of the rotors from 3,768,000 m^2 to 2,945,244 m^2. The amendment also requires analogous changes to conditions I.3.1 and I.3.4, as well as condition II.1.B.1 of the Environmental Decision. These changes are related to the development of wind farm implementation technologies. Wind farm manufacturers are putting into production power plants with ever-increasing capacity, which were not available at the time of the environmental decision. These newly available wind turbine sizes require an increase in certain wind turbine parameters, which at the same time allows for a significant reduction in the number of wind turbines installed. Thus, by introducing

[1] The Baltica offshore wind farm area covered by the PSZW issued for the Baltica 2 offshore wind farm and that issued for the Baltica 3 offshore wind farm were covered by a joint decision on environmental conditions. Decision on environmental conditions dated January 24, 2020, marked RDOŚ-Gd-WOO.4211.21.2017.MJ.PW.AJ.37 issued by the Regional Director of Environmental Protection in Gdansk for the project named "Baltica Offshore Wind Farm."

relatively minor changes in the parameters of the project regarding the maximum height of the power plant and the diameter of the rotor, it is possible at the same time to make a far-reaching reduction in the impacts both at the stage of implementation and operation of the planned project - detailed information in this regard can be found and Section 5 of Volume IV;

4. The change in point. I.1. The Environmental Decision Committee was asked to separately indicate the maximum area of the bottom occupied by 1 foundation of the power plant, setting it at 79 m^2, and separately the maximum area of the bottom occupied by 1 foundation of supporting infrastructure, setting it at 1,964 m^2, and to determine the total area of the bottom occupied by all foundations at 6,676 m^2. At the same time, an amendment to indicate that power plants will be able to be sited using a monopal or jacket type foundation;
5. Changing the wording of the condition on the number of wind turbines in a unit of space within the area designated for the development of power plants - point. I.3.3. According to this condition of the Environmental Decision, the maximum density of power plants can reach 1.35 units/km^2. The density parameter specified in the Environmental Decision describes the number of power plants per km^2 of the farm's area , while it does not specify in any way the distance between individual power plants and can lead to problems of interpretation. Therefore, it is proposed to replace the power plant density condition by specifying a minimum distance between power plants (counting from the axis of individual structures) of 800 m - see also Section 1 Volume II;
6. Removal from point I.1. Environmental Decision parameters describing the power, dimensions and weight of AC transformer stations and AC/DC converter stations. Since the planned maximum number of offshore substations has been reduced from 6 to 1, the final parameters of the substations may deviate from those indicated in the Environmental Decision, while these parameters do not affect the level and significance of the planned Project's environmental impact;
7. Amend the condition specified in Section II.1.A(a) of the Environmental Decision to differentiate the parameter determining the effectiveness of technical solutions to minimize underwater noise impacts according to the species requiring the solutions in question. It is proposed to establish the boundary sizes necessary to be maintained at the boundary of the nearest Natura 2000 area protecting marine mammals, i.e. Slavonian refuge PLH220023 at 140 dB re 1 µPa2s SELcum and weighted by the VHF function [a weighting function for cetaceans with high sensitivity to very high-frequency sounds] for porpoise, and 170 dB re 1 µPa2s SELcum and weighted by the PVC function [a weighting function for seals];
8. Adding another letter in point II.1.B of the Environmental Decision and in this newly added point indicating the exclusion from the possibility of locating the farm's over-water elements at the northwestern end of the body of water intended for the realization of OWF BIII, thus indicating the area allowed for the development of over-water elements in accordance with the coordinates presented in Table 1 in the application for amendment of the Environmental Decision. This condition is the implementation of the decision to exclude from wind power development a part of the BIII offshore wind farm area, for the purpose of creating an unobstructed migration corridor for birds between the groupings of wind power plants belonging to projects located on the northern and northeastern slopes of Slupsk Shoal, taken in consideration of the decision on environmental conditions issued for the Balitca 2 and Baltica 3 offshore wind farms;
9. Removal from Section II.2. The Environmental Decision in the section devoted to monitoring

the impact of the Project on seabirds and birds flying over the surface of the farm (including migratory birds) at the stage of operation of the provision on shutting down turbines located along the route of registered flocks of birds during migration periods. This provision does not address the scope and conditions of monitoring, and is inconsistent with the condition specified in section I.2.31 and I.3.12 of the Environmental Decision, which raises questions of interpretation;

10. Clarification of the condition specified in Section II.2. The Environmental Decision in the section on monitoring the impact of the Project on bats at the stage of operation by indicating that bat activity recorders will be deployed in no less than 6 in the first line of the power plant on the western and southern boundary of the BIII OWF area, which is justified by the characteristics of previous bat sightings in the area of the planned farm and the infrastructure of offshore wind farms planned by other investors, and repealing in this section the part of the condition concerning the study of bat mortality as part of post-implementation monitoring. In the case of bat mortality surveys, there are no methods that give reliable results for conducting such surveys in marine areas. The nature of the environment, including wave action, ocean currents, and the activity of animals picking up dead specimens, makes it impossible to reliably design bat mortality monitoring within OWF BIII. This change is also consistent with the rationale of the Environmental Decision, which indicates that bat monitoring should only be based on a survey of bat activity, and should be conducted on the same basis as monitoring prior to the Project;

11. Resignation of the condition stipulated in point IV of the Environmental Decision, i.e. the need to conduct a re-evaluation of the environmental impact as part of the procedure for issuing a construction permit. In the Environmental Decision in question, 6 reasons are indicated as the basis for imposing the obligation to re-evaluate the environmental impact, all of them no longer valid, which was influenced by both updates and clarifications of the conditions of the Project proposed in the course of the proceedings for which the Report was prepared, the change of factual circumstances resulting from both new knowledge and the decisions which were adopted in the decisions on environmental conditions for the projects of other offshore wind farms, and which significantly affect the execution environment of the OWF BIII project. Thus, maintaining the condition in question in the case of the other changes proposed in this Report would make a reassessment of the environmental impact an unnecessary administrative obligation that adds no new value to the goal of ensuring a high level of environmental protection. Detailed references to the various bases for imposing the obligation to reevaluate the environmental impact in the Environmental Decision can be found in Sections 3, 5, 6 and 7 of Volume II and in Volume V.

A summary of all proposed changes to the conditions set forth in the Environmental Decision can be found in Volume 5 (Summary) in Chapter 4 (Impact of the current parameters of the Project and the results of the impact assessment on the conditions set forth in the Environmental Decision for implementation, operation and decommissioning of the Project). In addition to the aforementioned changes, these are secondary changes to the points of the Environmental Decision as a consequence of taking into account the changes described above or consisting of clarifying interpretative doubts between the various provisions of the Environmental Decision, as well as changes aimed at increasing the level of protection of the marine environment by adding a requirement for visual observation and mammal deterrence prior to the start of bottom clearance operations by controlled explosion of

unexploded munitions by the relevant services.

3. Investor

The investor of the project is IMF Bałtyk III Sp. z o.o., 24/26 Krucza St., 00-526 Warsaw.

4. History of the project

The investor has been developing an offshore wind farm project in the area since 2011, originally under the name Bałtyk Środkowy III and then Polenergia Bałtyk III. The investor has a permit for the erection and use of artificial islands, structures and devices in Polish maritime areas for the project OWF Bałtyk Środkowy III No. MFW/2/2012 dated 30.03.2012.

On July 7, 2016. RDOŚ sign: RDOS-Gd-WOO.4211.12.2015.KSZ.22 issued a decision on environmental conditions for the project titled "Construction of offshore wind farm Baltic Central III." On the other hand, on January 4, 2022. The RDOŚ issued a decision confirming the validity of the project's conditions, which results in the possibility of submitting an Environmental Decision to obtain the decisions indicated in the catalog contained in Article 72 Section 1 of the AIA within 10 years from the date on which the decision on environmental conditions became final - in accordance with the provision of Article 72 Section 4 of the AIA.

Currently, the Investor, taking into account the significant advancement of preparations for the project and changes in the available sizes of wind turbines, as well as a much more advanced level of available knowledge on the environment in Polish maritime areas, the impacts caused by offshore wind farms, applies for an amendment to the decision on environmental conditions issued for the BIII OWF project.

5. Author team

1. Introduction

The energy industry is experiencing a period of extremely dynamic changes in the world, which are caused, on the one hand, by attempts to respond to climate threats caused, among other things, by the burning of fossil fuels, and, on the other hand, by technological advances that make it possible to implement solutions not available a decade ago, while significantly affecting the cost of investment implementation. Offshore wind energy is an area where it is positively stimulated by both factors indicated. Nevertheless, the development of offshore wind energy to date has faced developmental problems in Polish conditions, which have not allowed to use the autos of this technology.

However, the modernization challenges facing the Polish energy sector make solutions that diversify Poland's sources of energy acquisition, especially in combination with ensuring low-carbon or non-carbon energy sources, not only prospective, but timely and highly desirable. To date, the development of offshore wind energy has largely been through climate policy, as defined in a series of documents at the international, EU and national levels. However, it is to be expected that market factors will become important in the coming years, both in the dimension of the cost of energy production, as well as consumers' expectations in terms of energy sources. However, regardless of the increased importance of these factors, the role of international and domestic policy instruments will be very important in this area. The following are the most important strategic documents on which the environmental objectives of the BIII OWF may be affected. It should be emphasized, however, that some of the analyzed documents are firmly rooted in the realities of the passing decade and will need to be revised and updated in the face of changing conditions and trends.

2. International and EU strategic documents strategic

2.1. International and European energy and climate policies climate

Climate change, but also the international community's response to it, is currently the most important subject of discussion in all forums of international cooperation. The need for solutions at the global level is not only demanded by the scientific community, but is reflected in international documents. Concluded in December 2015 as part of the United Nations Framework Convention on Climate Change, the Paris Agreement is currently the main document setting out the goals of the signatories - the parties to the agreement - to combat climate change. The Covenant's strategic environmental goal is to contain the rise in global temperature in the second half of this century to at least 2°C, and if possible even 1.5°C.

The system of national emission reduction targets introduced by the European Union aims to reduce member states' greenhouse gas emissions by 2030 as envisioned by the Paris Agreements.

The policy framework was adopted by EU leaders in October 2014. It is an extension of the Climate and Energy Package to 2020, and is in line with the long-term outlook set forth in the Roadmap for moving to a competitive low-carbon economy by 2050, the Energy Roadmap 2050, the Clean Energy for All Europeans Package (the so-called Winter Package), and especially Directive (EU) 2018/2001 of the European Parliament and of the Council of 11 December 2018 on the promotion of the use of energy from renewable sources. The framework strategy for a stable energy union based on a forward-looking

climate policy envisions, among other things, reducing emissions by promoting investment in new technologies, such as offshore wind farms.

The primary environmental goals for 2030 are:

- a reduction of at least 40% in greenhouse gas emissions (relative to 1990 levels);
- ensure at least 32% of the share of renewable energy in total energy consumption;
- increasing energy efficiency by at least 32.5%.

However, it should be emphasized that the European Union's climate policy is increasingly oriented towards accelerating the path of achieving greenhouse gas emission reductions. The premise of the European Union's new strategy, the European Green Deal, is to achieve climate neutrality by 2050 and decarbonize the energy sector. The proposed legislative solutions will still be the subject of work in the European Council and the European Parliament, nevertheless, the documents presented by the European Commission as implementing the new strategy envisage building an energy sector based to a greater extent on renewable sources, including the full use of the potential of offshore wind energy - proposing to raise to 40% the share of energy produced from renewable sources and to reduce greenhouse gas emissions by at least 55% by 2030.

2.2. Building a climate-resilient Europe - the EU's new Climate Change Strategy on adaptation to climate change, Brussels 2021

The strategy is a complementary document to the European Green Deal strategy. A key objective of the Strategy is to make EU society resilient to climate change and fully resilient to the inevitable effects of climate change. According to the adopted assumption, this goal is to be achieved in 2050, as a result of the implementation of a series of actions in three areas of increasing resilience to climate change, viz:

- filling knowledge gaps on climate change impacts and resilience solutions by creating an extensive knowledge base on which effective adaptation actions will be taken. The need for more knowledge stems from uncertainty about the pace and extent of climate change and its effects on natural and man-made ecosystems;
- making adaptation efforts more systemic. The strategy calls for improving national and regional adaptation plans and strategies as instruments for a systemic approach to climate change adaptation. The need to integrate climate resilience into the budget policies of member states is considered necessary action in this area - introducing procedures for processes and tools to counteract ex ante climate risks and eliminate ex post impacts of natural disasters.
- introduce nature-based solutions on a larger scale - in cities or other large infrastructure facilities, it is crucial to increase the importance of blue-green infrastructure by developing green urban spaces and building green roofs and walls; at the ecosystem level, work leading to increased protection and restoration of wetlands, peatlands, coastal and marine ecosystems, and promoting and carrying out sustainable management of forests and agricultural land in a cost-effective manner needs to be intensified.

The strategy calls for an overall acceleration of adaptation to climate change. To this end, the Union is to increase the target level of spending on climate action to 30% in its long-term budget for 2021-2027. The second step needed to accelerate adaptation is to invest in sustainable, climate-resilient infrastructure. Widespread use of insurance as a risk transfer mechanism to cover financial losses associated with climate risk may become a necessary endeavor

2.3. Directive 2014/89/EU - maritime spatial planning maritime areas

Directive 2014/89/EU of the European Parliament and of the Council of 23 July 2014 *establishing a framework for maritime spatial planning* (OJ. EU. L. 257 of 2014, p. 135) ("Directive 2014/89/EU") aims to promote:

- sustainable growth in the maritime economy;
- sustainable development of marine areas;
- sustainable use of marine resources.

Directive 2014/89/EU imposes a legal requirement on EU member states to create transparent maritime planning systems and cooperate with neighbors to do so. When establishing maritime spatial planning, Member States shall take due account of the specific characteristics of maritime regions and the relevant existing and future activities and uses of these areas, their impact on the environment and on natural resources, and shall take into account the interaction between land and sea (Article 4(5) of Directive 2014/89/EU). Directive 2014/89/EU notes the need to maintain an integrated approach in the planning process, involve and consult stakeholders, use the best available data and information, take into account the interaction between land and sea, ensure cross-border cooperation between member states, and promote cooperation with third countries.

The provisions of the Directive establishing a framework for maritime spatial planning were implemented into Polish law primarily by the Act of March 21, 1991 *on maritime areas of the Republic of Poland and maritime administration* (consolidated text Dz. U. of 2020, item 2135, as amended).

2.4. Convention on the Protection of the Marine Environment of the Baltic Sea Area, done at Helsinki on April 9, 1992. - Helsinki Convention

Convention on the Protection of the Marine Environment of the Baltic Sea Area, done at Helsinki on April 9, 1992. (Journal of Laws of 2000, No. 28, item 346) - ("Helsinki Convention") ("HELCOM"), which came into force on January 17, 2000, covers the entire Baltic Sea area, including inland waters, as well as the waters of the sea itself and its bottom. All measures are also being taken to reduce pollution throughout the Baltic Sea basin.

The 1992 Helsinki Convention, concerns the protection of the Baltic Sea environment from pollution by harmful substances from all possible sources and from adverse effects through energy (e.g. radiation, inducing temperature changes). It also includes provisions for the protection of coastal flora and fauna.

Of key importance among the Convention's provisions is the provision obliging the Contracting States to take all measures that become necessary to ensure the protection of the Baltic marine environment and the ecological restoration of the Baltic region (Article 3).

Importantly, HELCOM has determined that marine Natura 2000 sites meet the criteria for inclusion in HELCOM's network of marine protected areas.[1] The way in which environmental protection is established and implemented in Natura 2000 areas that overlap with the Baltic Marine Conservation

[1] EC, Guidelines for the establishment of Natura 2000 networks in the marine environment. Application of the Habitats and Birds Directives, Brussels 2007, p. 11.

Areas must be in accordance with the content of the Helsinki Convention and the recommendations issued by HELCOM.

3. Implementation of the project in the context of national strategic and planning documents planning

3.1. Long-term National Development Strategy ("DSRK")

The DSRK is a document that defines the main trends, challenges and scenarios of the country's socio-economic development and the directions of the country's spatial development, taking into account the principle of sustainable development. It is an overarching document whose development goals will be implemented through the country's medium-term development strategy and through nine integrated strategies.

One of them is the strategic area "Energy Security and Environment" (BE&E), which has the main goal of ensuring an optimal amount of energy at the lowest possible prices and diversifying the sources and routes of energy carriers. The key environmental goals are the process of reducing CO2 emissions and air pollution. It is also important to take measures for the efficient use of environmental resources.

3.2. Strategy for responsible development (SOR)

The Strategy for Responsible Development is an update of the country's medium-term development strategy. The document sets out the principles, goals and priorities for the country's development in the economic, social and spatial dimensions until 2020, but in the perspective to 2030. The strategy deliberately assumes a longer time horizon as a response to shortcomings in the area of instruments supporting the implementation and monitoring of the long-term strategy. The Strategy defines its main objective as the creation of conditions for an increase in the income of Poland's population with a simultaneous increase in social, economic, environmental and territorial cohesion. The following were identified as specific objectives:

- Sustainable economic growth based increasingly on knowledge, data and organizational excellence;
- Socially responsive and territorially sustainable development;
- An effective state and institutions for growth and social and economic inclusion.

For the achievement of both the main and specific goal, strategic projects have been formulated. Among them, in the context of this document, the project stands out: Strategy for Transformation to a Low Carbon Economy and Clean Air. The first is to develop an implementation framework for decarbonizing and reducing the energy intensity of the economy. The Clean Air Project, on the other hand, focuses on activities related to improving air quality, particularly through the elimination of emission sources and the introduction of quality requirements for solid fuels.

3.3. National Environmental Policy 2030 (PEkP 2030)

The National Environmental Policy 2030 was adopted in 2019, and it is one of nine sectoral strategies under the Law on the Principles of Development Policy. By the same token, the enacted National Environmental Policy 2030, together with the future Energy Policy of Poland until 2040, will fill in the area of state policy that has so far been defined by the Energy Security and Environment (E&E) strategy.

The National Environmental Policy was built on the basis of 3 specific goals, i.e. Environment and Health, Environment and Economy, and Environment and Climate, and complemented by two horizontal goals Environment and Education and Environment and Administration. Among the directions of intervention particularly relevant from the point of view of the connection with the planned project is direction 7.10 Counteracting climate change. It assumes further efforts to reduce greenhouse gas emissions, with renewable energy sources along with a proper management system identified as one way.

3.4. Energy Policy Poland

The current Polish Energy Policy until 2040 ("PEP 2040") outlines the future directions and goals of Poland's energy policy. The Energy Policy of Poland defines the goals of the state policy The document indicates that the goal of the state energy policy is energy security while ensuring the competitiveness of the economy and energy efficiency and reducing the environmental impact of the energy sector. Among the indicators for achieving the goals is also the 23% share of RES in gross final energy consumption in 2030.

In 2020, Poland's Climate Ministry presented assumptions for a draft update of Poland's energy policy - the Energy Policy of Poland until 2040. One of the pillars of the proposed document is a zero-carbon energy system. One of the specific objectives for the implementation of the energy policy pillars identified is the development of renewable energy sources (Specific Objective 6), and within this framework the strategic project - Implementation of offshore wind energy - is to be implemented.

The document stresses that the energy policy will seek to fulfill the commitment contained in the above EU strategies. The goal, therefore, is to realize the pledges made: in the long term, a Europe that is a low-carbon economy and a secure, sustainable and competitive energy supply. Assumed environmental goals include balancing key emissions (CO2).

3.5. Concept for Spatial Development of the Country 2030 ("KPZK")

The NCP was adopted by Resolution No. 239 of the Council of Ministers on December 13, 2011. (M.P.2012.252). It is the main document on spatial development in the long term, and defines the goals and directions of the country's spatial development policy. The development of offshore wind farms is included in the document as a tool for improving the country's energy security. The NCP specifies that wind power will account for 45% of the energy obtained from RES. According to the findings of the NAP 2030, the planned project is located in the zone of distributed renewable wind energy development. The NAP 2030 sets 6 goals that implement the strategic objective. Relevant to the implementation of the project, the environmental goals of the NSPCC are the diversification of energy sources, resulting in a reduction in CO2 emissions, including the development of RES.

3.6. Spatial development plan for Polish maritime areas ("PZPPOM")

The spatial development plan for the Polish maritime areas of internal waters, territorial sea and exclusive economic zone at a scale of 1:200000 was adopted as of April 14, 2021.[2]

The plan, was prepared jointly by the directors of the Maritime Offices in Szczecin, Slupsk and Gdynia, so as to ensure consistency of spatial development of the entire plan area. The plan covers the entirety of internal waters, the territorial sea and the exclusive economic zone under the jurisdiction of the Polish maritime administration, excluding the waters of ports and three lagoons, for which, due to the scale of conflicts and the intensity of interactions between land and sea, plans will be drawn up on a larger scale so that detailed issues can be included in them.[3] The area POM.45.E is designated in the Plan for the purpose of obtaining renewable energy, while internal and external technical infrastructure are considered integral to projects of this kind. Thus, the Plan takes into account the implementation of the BIII OWF in the area in question. The Plan indicates restrictions related to the use of space, including technical infrastructure:

- it is limited to the infrastructure necessary for the energy acquisition function;
- is limited to ways that do not ecologically threaten the function of spawning grounds and the survival of the early life stages of fish (eggs and larvae) of commercial species;
- it is required to lay linear elements of technical infrastructure in a space-saving manner, under the surface of the seabed, and if this is not possible for environmental or technological reasons, other permanent protection should be used, allowing the safe use of anchored pond nets.

The plan, in the section defining the conditions of use of the basin for obtaining renewable energy, indicates that:

- the area is dedicated to obtaining energy from wind through wind turbines, recognizing internal and external technical infrastructure as part of projects serving this purpose;
- at the time of commencement of the project of erecting artificial islands and structures, it is required to introduce, by a decision of the territorially competent director of the maritime office, a ban on fishing and navigation in the body of water occupied after construction, along with a 500-meter safety zone around the body of water, for the duration of construction;
- during the operation of offshore wind turbines, it is required to introduce, by decision of the territorially competent director of the maritime office, restrictions on fishing and navigation in the safety zones established for each structure and in places that threaten the safety of the internal technical infrastructure.

The plan takes into account the permit for the erection and use of artificial islands, structures and devices in Polish maritime areas issued to the Investor for the subject body of water with the reference GI7/62/1170069/Decision/2012 by the Minister of Transport, Construction and Maritime Economy on March 30, 2012.

3.7. Maritime Policy of the Republic of Poland until 2020 with an Outlook until 2030 ("PMRP")

In the PMRP adopted by the Council of Ministers on March 17, 2015. The PMRP determined that the real potential for offshore wind energy development in Poland, which can bring the greatest benefits to

[2] Ordinance of the Council of Ministers of April 14, 2021 on the adoption of a spatial development plan for internal marine waters, territorial sea and exclusive economic zone at a scale of 1:200,000 (Journal of Laws of 2021, item 935)
[3] https://legislacja.rcl.gov.pl/projekt/12345201/katalog/12776609#12776609, accessed May 2022.

the Polish energy balance and the Polish economy, is 6 GW of installed capacity in offshore wind farms by 2030, with 1 GW in 2020 and another 2 GW by 2025. The creation of conditions for the construction of offshore wind farms was identified as a measure to improve energy security.

3.8. National Energy and Climate Plan 2021-2030 (NERP)

The National Energy and Climate Plan was developed by an inter-ministerial team under the coordination of the Ministry of State Assets, and it implements the obligation under Regulation (EU) 2018/1999 of the European Parliament and of the Council of December 11, 2018. on Governance of the Energy Union and Climate Action, amending Directive 94/22/EC, Directive 98/70/EC, Directive 2009/31/EC, Regulation (EC) No. 663/2009, Regulation (EC) No. 715/2009, Council Directive 2009/119/EC, Directive 2010/31/EU, Directive 2012/27/EU, Directive 2013/30/EU and Council Directive (EU) 2015/652 and repealing Regulation (EU) No. 525/2013. The document, after adoption by the Committee on European Affairs, was forwarded to the European Commission on December 30, 2019.

The NAPE outlines assumptions and goals, as well as policies and actions to implement the 5 dimensions of the energy union, i.e.

1. energy security,
2. internal energy market,
3. energy efficiency,
4. decarbonization and
5. research, innovation and competitiveness.

The National Energy and Climate Plan 2021-2030 sets the following climate and energy targets for 2030:

- -7% reduction in greenhouse gas emissions in non-ETS sectors compared to 2005 levels,
- 21-23% share of RES in gross final energy consumption (the 23% target will be achievable if Poland is granted additional EU funds, including those earmarked for a fair transition), taking into account:
    - ⇒ 14% share of RES in transportation,
    - ⇒ annual increase in the share of RES in heating and cooling by 1.1 percentage points on average per year,
- a 23% increase in energy efficiency compared to PRIMES2007 projections,
- reducing to 56-60% the share of coal in electricity generation.

The NERP includes measures to support renewable energy sources in its stated goals, while indicating that offshore wind generation sources will account for the largest amount of energy generated from renewable energy sources, projecting the capacity achieved from these sources at 3.8 GW in 2030 and about 8 GW in 2040.

3.9. National program for the protection of marine waters ("NTPP")

According to Article 145 of the Water Law, the environmental goals for marine waters are achieved by taking measures specified in the National Marine Waters Protection Program, adopted by the Council of Ministers by decree on December 11, 2017. (Journal of Laws of 2017, item 2469).

The NEB is a strategic document required to be developed by the Maritime Strategy Framework Directive (MSFD) for member countries. The goal of the NSPOWM is to identify the optimal set of measures that will lead to the achievement of good environmental status of marine waters within a specified time.

The set of environmental objectives for marine waters is set forth in the Regulation of the Minister of Environment of 17.02.2017 on the adoption of a set of environmental objectives for marine waters (Journal of Laws 2017, item 593) issued on the basis of Article 61o paragraph 8 of the Act of 18 July 2001. - Water Law (i.e. OJ. U. of 2021, item 2233, as amended). This act defines environmental objectives for 11 categories of characteristics - descriptors that, according to the provisions of the RDSM, constitute criteria for assessing the good state of the marine environment (Annex I to the RDSM).

A preliminary assessment of the state of the marine environment, as required by the ICZM, was prepared in 2013 by the Chief Inspector of Environmental Protection and adopted by the Council of Ministers on November 10, 2014. This assessment is used to obtain information on the current state of the marine environment, and thus serves as a starting point for determining the courses of action needed to be implemented to achieve the goals set by the ICZM. Criteria and methodological standards for measures of achieving good environmental status of marine waters are set out in European Commission Decision 2017/848/EU. In connection with the obligation to update the assessment of the state of the environment of marine waters in 6-year cycles, an update of the preliminary assessment of the state of the environment of the Polish Baltic Sea zone covering the years 2011-2016 was published by the Chief Inspector of Environmental Protection in 2019. Updating the assessment provides a basis for verifying the effectiveness of measures taken to achieve environmental goals for marine waters, and thus modifying the national marine water protection program.

As part of the Project's impact assessment, an analysis was made of the impact of the proposed changes to the Project previously subjected to the impact assessment on changes in the nature and extent of potentially generated impacts, and consequently on the ability of the modified Project to affect the state of marine waters and the ability to achieve a set of environmental objectives set for them and the national marine water protection program (see Section 4 below).

3.10. Pomorskie Region Development Strategy 2030 ("SRWP")

The SRWP is the basic strategic document guiding the development of Pomorskie Voivodeship. It was adopted by the Sejmik of Pomorskie Voivodeship by Resolution No. 376/XXXI/21 of April 12, 2021. The strategy sets strategic and operational objectives and directions of activities. The planned project is in line with Operational Objective 1.2 Energy security.

The SRWP points to climate change risks identified as one of the key threats to the region. The development directions will emphasize low-carbon and renewable energy as a desirable development direction, while highlighting the opportunity of offshore wind energy development.

3.11. Pomeranian Voivodeship Spatial Development Plan 2030 ("PZPWP")

The PZWP was adopted by Resolution No. 318/XXX/16 of the Pomeranian Regional Assembly on December 29, 2016. Electricity production and the transformation of the region into a national leader

in renewable energy production is one of the main goals and objectives of the Plan. For the realization of the BII offshore wind farm, it is important to include among the activities and projects of the 2030 FMP the construction of transmission networks and substations for the derivation of power from new system and renewable energy sources, including offshore wind farms. PZPWP 2030 also indicates the possible and expedient activation of port and shipyard areas for offshore development activities, including, for example, a logistics and service and maintenance center for offshore wind farms in the ports of Leba, Ustka and Władysławowo.

4. Implementation of the project and the environmental objectives arising from strategic and planning documents planning documents

4.1. Environmental objectives of documents from the areas of energy, climate, economic development and land use

Table 1. Analysis of the environmental objectives arising from the strategic documents relevant to the implementation of the Project in terms of its relevance to the strategic objective

European documents	
Strategic objective relevant to the implementation of the Project	**Relevance of the Project in the context of the stated strategic objective**
EU Strategy for the Baltic Sea Region	
Goal Save the Sea: • sub-goal - clean sea water - activities under this goal focus on combating eutrophication; • sub-goal - rich and healthy animate nature; • measures to protect and counteract the loss of biodiversity.	The impact on water quality will be temporary and insignificant and will not contribute to the inability to achieve or maintain good water status. The low impact of the project during the construction phase of the farm on the occurrence of species and habitats and the low impact during the operation period should ensure that there is no conflict with the goal of preserving biodiversity.
Goal Increase Prosperity: • sub-goal - climate change adaptation, mitigation and risk management - measures to adapt and mitigate the impact of climate change.	Implementation of the project does not conflict with the goals of the plan. Construction of the BIII offshore wind farm will have a positive impact on reducing climate change pressures and will be neutral to climate change adaptation measures.
A clean planet for all. European long-term strategic vision for a prosperous, modern, competitive and climate-neutral economy, 2018	
The goal of the Strategy is to present a vision that can achieve zero net greenhouse gas emissions by 2050 through a socially equitable and cost-effective transition. The Strategy underscores the opportunities this transformation creates for the Union's citizens and its economy, and identifies future problems. It is intended to set the course for EU climate and energy policy and give shape to what the EU sees as its long-term contribution to the Paris Agreement's temperature goals,	Implementation of the project will contribute to reducing the environmental impact of the energy industry, due to the replacement of the use of fossil fuels in energy generation with non-emitting technology. It fits directly into the goal of maximizing the use of renewable energy sources. The impact on marine water quality will be temporary and insignificant and will not contribute to the inability to achieve or maintain good water status. The way the farm is designed

consistent with the UN Sustainable Development Goals. The document sets out proposed courses of action until 2050 in 7 strategic areas, of which the important ones from the point of view of the planned Project are: 1. Maximize the benefits of energy efficiency, including zero-emission buildings. 2. Maximize the use of renewable energy sources and electricity to completely decarbonize Europe's energy supply. 3. Adopting clean, safe and network-based mobility. Competitive EU industry and closed-loop economy as key enabler to reduce greenhouse gas emissions	and constructed is to ensure that pressure on marine waters is kept as low as possible. At the same time, the implementation of the project does not interfere with the possibility of achieving environmental goals for marine waters.
Building a climate-resilient Europe - the EU's new Climate Change Adaptation Strategy, Brussels 2021	
The EU's 2021 Adaptation Strategy complements the one published in 2019. European Green Deal. A key objective of the Strategy is to make EU society resilient to climate change and fully resilient to the inevitable effects of climate change.	Implementation of the project will only have a minor impact on the Baltic Sea ecosystem, mainly during the construction phase. During the operational period, the project will not contribute to the deterioration of ecosystems and their functions. Appropriate design and implementation of the Project will not conflict with climate change adaptation activities.
EU biodiversity strategy 2030	
The Strategy includes a number of commitments, showing 2030 as the horizon for achieving them. Among the main goals are: - the creation of a larger network of protected areas on land and at sea throughout the EU; - launching a plan for the restoration of natural resources; - introduce measures to enable the necessary transformational change - the need to free up funding for biodiversity and apply a new, strengthened governance framework to ensure better implementation of the Strategy and track progress; raise awareness and increase funding and investment; - ensure better respect for nature in public and business decision-making.	Implementation of the project will have little impact on the Baltic Sea ecosystem. During the period of operation, the project will not contribute to the deterioration of ecosystems and their functions, and with regard to fish and benthic habitats, it may promote improved habitat and development due to the existence of exclusion zones from anchoring or certain forms of fishing and restrictions on vessel traffic.
European Landscape Convention	
Integrate the landscape into its own regional and urban planning policies, and its own cultural, environmental, agricultural, social and economic policies, as well as any other policies that directly or indirectly affect the landscape.	The project will not affect policies related to ensuring landscape protection in regional and local planning. The project's impact on the coastal landscape will not be negative due to its significant distance from the shore.

National documents	
Concept of Spatial Development of the Country 2030	
Objective 4. Shaping spatial structures that support the achievement and maintenance of high quality of the natural environment and landscape values of Poland: 4.1. integration of activitieś in the operation of a coherent ecological network of the country as a basis for the protection of the most valuable natural and landscape resources; 4.2. countering fragmentation of natural space; 4.3. introduction of landscape management in accordance with the provisions of the European Landscape Convention; 4.4. to rationalize the management of the country's limited surface and groundwater resources, including preventing the occurrence of water deficits for the needs of the population and economic development; 4.5. achieve and maintain the good status and potential of water and related ecosystems; 4.6. reduce the environmental burden caused by emissions of pollutantś to water, atmosphere and soil.	The degree of the project's impact on the country's ecological network and the most valuable natural and scenic resources is small, limited mainly to the construction phase and, with respect to birds, the operation phase. There will be no permanent fragmentation of natural space due to measures to minimize the barrier to migratory birds, including migration corridors. The impact on water quality will be temporary and insignificant, and will not contribute to the inability to achieve or maintain good water status. Implementation of the Project may contribute to reducing the environmental impact of energy, due to the replacement of fossil fuels with a renewable, non-emitting energy source such as wind.
National Environmental Policy 2030.	
Direction of intervention - Tackling climate change. Task - Support for investments related to the increase of production from renewable sources	The planned Project is in line with the proposed policy directions and contributes to the goal for which the direction was formulated
Direction of intervention - Management of natural and cultural heritage resources, including protection and enhancement of biological and landscape diversity, task - Protection of species and habitats of the Baltic Sea and effective management of Natura 2000 marine areas	The method of implementation of the Project and the provided minimization measures are constructed in such a way as to minimize the potential for negative impacts. The environmental impact assessment for the project showed no significant impacts. The proposed changes to the project further reduce the potential for impacts on protected species and habitats in marine areas
Poland's Energy Policy to 2040.	
Poland's energy policy defines the objectives of state policy, indicating that it is energy security while ensuring the competitiveness of the economy and energy efficiency, and reducing the environmental impact of the energy sector. Among the indicators for achieving the goals is also the 23% share of RES in gross final energy consumption in 2030.	Taking into account the higher emissivity of fossil solid fuels in relation to wind energy, the implementation of the Project will be in line with the goals of reducing the impact of energy on the environment, in particular, it will be directly in the implementation of strategic projects Implementing offshore wind energy under specific objective 6. Development of renewable energy sources.
Program for the conservation and sustainable use of biodiversity with an Action Plan for 2015-2020	

Objective 3. Maintenance and restoration of ecosystems and their services.	The minor impact of the project during the construction phase on benthic habitats, marine mammals and fish, and the minor impact during the operation period on birds will result in an insignificant impact on the Baltic Sea ecosystem. To a certain extent, due to the existence of zones excluded from anchoring or certain forms of fishing and vessel traffic, the implementation of the project may have a positive impact.
Objective 4. Ensure sustainable use of fishery resources.	To some extent, due to the existence of zones excluded from anchoring or certain forms of fishing, the implementation of the project may have a positive impact.
Objective 5. Control of invasive alien species.	The assessment made at the report stage prior to the issuance of the environmental decision remains valid, ie: The venture will be implemented in the waters of the Baltic Sea. The manner in which the work is carried out and the sources of materials used in the implementation of the Project should ensure that there is no conflict with the objective.
Strategic adaptation plan for sectors and areas vulnerable to climate change until 2020 with an outlook to 2030	
Goal - Ensure energy security and a good environment: • direction of action - adaptation of the coastal zone to climate change; • course of action - adaptation of the energy sector to climate change.	Implementation of the Project does not conflict with the objectives of the plan. Appropriate design and implementation of the project will not conflict with climate change adaptation measures. Implementation of the project can contribute to the direction of action related to adaptation of the energy sector to climate change.
Pomeranian Voivodeship Development Strategy 2020	
Objective 1.2 Energy security	The project fits directly into this goal as part of achieving climate neutrality. The project coincides with the goals of developing renewable energy sources and improving air quality.

4.2. Environmental objectives for waters marine

The conservation principles and targets for marine waters set out in the Marine Strategy Framework Directive require Member States to take the measures necessary to achieve or maintain good environmental status of marine waters by 2020 at the latest.

In the Polish legal order, the state's obligations to achieve the ICZM goal of good status of marine waters and the tools for achieving it are defined in the Act of July 20, 2017. *Water Law* and executive acts to this law.

An act of particular importance, for the analyses conducted in this report, is the Regulation of the Minister of Environment dated February 25, 2021 *on the adoption of a set of environmental objectives for marine waters*. This act defines environmental objectives for 11 categories of characteristics - descriptors that, according to the provisions of the RDSM, constitute criteria for assessing the good state of the marine environment (Annex I to the RDSM). The distinguished goals include features of indicators of environmental status (D1, D4), as well as indicators of environmental pressure (D2, D3, D5, D6, D7, D8, D9, D10, D11). The objectives set by the regulation for Polish marine waters are shown in Table 2.

Table 2. Summary of environmental objectives for marine waters broken down into 11 categories of features - descriptors

	Feature - descriptive indicator for which the target is set	Description of the objective
D1	Biodiversity	Reduce or maintain anthropogenic pressure at a level that ensures the maintenance of natural habitats, where the natural biodiversity of the biotic elements present is preserved, including in fisheries, and habitat protection within Natura 2000 protected areas is ensured.
D2	Foreign species	Reduce the possibility of the spread of alien species introduced into the environment as a result of human activities to ensure the occurrence of alien species at levels that do not disrupt the structure and functioning of the ecosystem, especially with regard to specific groups of species, areas particularly vulnerable to introduction, and general habitat types, by taking appropriate measures.
D3	Commercially exploited fish and shellfish species	maintaining populations of commercially exploited fish and shellfish within safe biological limits corresponding to natural conditions by ensuring that the exploitation of all commercially exploited fish stocks is at or below the level of maximum sustainable yield ensuring that all commercially exploited fish are within safe biological limits, and by limiting or maintaining the exploitation of fish stocks at a level that ensures that their full reproductive capacity and full range of individual ages and sizes are maintained.

	Feature - descriptive indicator for which the target is set	Description of the objective
D4	Food chain	Reduce the impact of human activities to a level that allows the ecosystem to reach a state in which all elements of the marine trophic chain exhibit a natural and stable level of abundance and diversity, and the productivity of biotic components ensures the proper functioning of the trophic network.
D5	Eutrophication	Maintain the inflow of annual loads of nitrogen and phosphorus carried into the Baltic Sea by rivers and in the form of atmospheric deposition below the maximum inflow values (MAI) established within the framework of regional arrangements (HELCOM), which will allow to reduce the concentration of nutrients in the sea to a level that does not exceed permissible threshold values, which are in accordance with the recommendations of the applicable national and European Union acts, and which guarantee the achievement or maintenance of good environmental status and do not cause negative effects in the form of excessive algal growth, elevated concentrations of chlorophyll "a" in the water column, a decrease in the transparency of seawater and the level of oxygenation of bottom waters, which consequently promote the proper development of pelagic and benthic habitats.
D6	Seabed integrity	Reduce cumulative pressure on the seabed to a level that allows benthic habitats to function at a near-natural level.
D7	Hydrographic conditions	Reduce pressures associated with permanent changes in hydrographic conditions. Reduce cumulative pressures on habitats.
D8	Pollutants and their effects	Reduction or maintenance at the current level of the inflow of pollutants, originating from marine sources, including the application of measures to minimize releases of pollutants as a result of emergency events, and land-based pollutants entering the marine environment, in order to achieve or maintain concentrations of pollutants in biotic and abiotic elements of the marine ecosystem at levels that do not exceed permissible thresholds, below which the probability of undesirable effects of hazardous substances on marine organisms is minimal and which are in accordance with the recommendations of applicable national and international legal acts, and which guarantee the achievement or maintenance of good environmental status.
D9	Contaminants in fish and shellfish for consumption	Reduce or maintain the influx of pollutants (hazardous) from various marine and terrestrial sources entering the marine environment, in order to achieve or maintain the

	Feature - descriptive indicator for which the target is set	Description of the objective
		concentrations of pollutants (hazardous) in fish and shellfish for human consumption at levels that do not exceed permissible values, which are in accordance with the standards and provisions of applicable national and international legal acts and which guarantee the achievement of good environmental status.
D10	Waste in the marine environment	Reduce the amount of newly emerging and deposited solid waste in the marine environment from various land and marine sources to levels that guarantee the proper functioning of the ecosystem, taking into account the natural resilience of the ecosystem, or to eliminate newly emerging waste altogether.
D11	Underwater noise	Reduce pressures associated with the temporal and spatial occurrence of impulse sounds in the sea associated with human activities, above levels that have a negative impact on marine animal populations. Reduce pressures associated with the temporal and spatial occurrence of continuous low-frequency sounds in the sea associated with human activities, above levels that have a negative impact on marine animal populations.

The Regulation on Adopting a Set of Environmental Objectives for Marine Waters also divides Polish marine waters into basins where monitoring and diagnostics of the current state of marine waters are carried out. From the point of view of the Project, the body of water for which it is necessary to assess the impact on the possibility of achieving the goals set for good environmental status of marine waters is: the Bornholm Basin body of water (formerly: body of water No. 36 - open waters of the Bornholm Basin).

According to the requirements of the IODR, Member States were required to conduct a preliminary assessment of the state of the marine water environment by 2012. The preliminary assessment of the state of the marine water environment was prepared in 2013 by the Chief Inspector of Environmental Protection and adopted by the Council of Ministers on November 10, 2014. The assessment is used to obtain information on the current state of the marine environment, and thus serves as a starting point for determining the courses of action needed to be implemented to achieve the goals set by the ICZM. This assessment is carried out for all 11 characteristics - descriptive indicators, which are the criteria for assessing the good condition of the marine environment. Criteria and methodological standards for measures of achieving good environmental status of marine waters are set out in European Commission Decision 2017/848/EU. Assessment results for all 11 traits-descriptive indicators were defined in two classes: good state (GES) and below good state (subGES). As noted above, in order to take into account the applicable classification for transitional and coastal waters under the WFD, the boundaries of good and below good status were adopted to run in line with the lower limit of good water status according to the WFD classification.

Member States are required to update the original assessment of the state of the environment every six years (similarly, an update of the environmental objectives and the adopted program of measures

to achieve the goals of the ICZM is required. In 2019. The Chief Inspector of Environmental Protection published an Update of the Preliminary Assessment of the Environmental Status of the Polish Baltic Sea Area covering the years 2011- 2016.

A summary of the 2018 updated assessment of the state of the marine environment by 11 features - descriptors for the Bornholm Basin is presented in Table 3. The environmental goals for all marine areas within Polish jurisdiction have been set uniformly. The table also summarizes the importance of activities undertaken in the implementation of the Project,

relevant to achieving the goals of good marine environmental status and the nature of potential impacts. The table also indicates the relevant chapters of this Report with more detailed information related to the impacts so identified.

Table 3. Environmental objectives established for marine waters in the zone of influence of the Project

Feature-Descriptive Indicator/Place of Analysis in Report	Current status of the Bornholm Basin basin	Link to the Project	Potential impacts	Assessment of the impact of the Project on environmental objectives [affects - YES/does not affect - NO]
D1. Biodiversity Chapter: T IV R 13.	subGES - for mammals, breeding birds, fish and benthic habitats, GES for wintering birds and pelagic habitats	Ensure the protection of biodiversity in the Project area, maintaining the habitats in the area in a state corresponding to their natural conditions. Ensure proper conditions for sensitive species occurring in the area of influence of the project (such as porpoise).	Disturbance of the structure of the seabed; Release of pollutants and nutrients from bottom sediments; Sedimentation of agitated sediments; Presence of steel/concrete structures and cables; Underwater noise; Risks associated with the spread of alien species; Flushing during construction work.	NO
D2. Foreign species Chapters: T IV: R 3, R 4, R 5, R 6, R 7.	subGES	Risk of introducing new alien species during the implementation and operation phases of the project.	The spread of alien species.	NO

Feature-Descriptive Indicator/Place of Analysis in Report	Current status of the Bornholm Basin basin	Link to the Project	Potential impacts	Assessment of the impact of the Project on environmental objectives [affects - YES/does not affect - NO]
D3. Commercially exploited fish and shellfish species Chapters: TIV: R 4, R 10.	no aggregated indicator for the whole trait, subGES for sprat, GES for herring	Occurrence of fishing areas in the farm area.	Disturbance of the structure of the seabed; Release of pollutants and nutrients from bottom sediments; Sedimentation of agitated sediments; Presence of steel/concrete structures and cables; Underwater noise.	NO
D4. Food chain Chapters: TIV: R 2,R 3,R 4, R 5, R 6, R 7, R 10.	subGES for all trophic groups A, B, C	Occurrence of species at the top of the food chain in the project area. Their presence may indicate good conditions for the functioning of the food chain.	Disturbance of the structure of the seabed; Release of pollutants and nutrients from bottom sediments; Sedimentation of agitated sediments; Presence of steel/concrete structures and cables; Underwater noise.	NO
D5. Eutrophication Chapter: TIV R 2.	subGES	Construction work, including installing foundations, burying cables and making embankments of rock material, anchoring can cause agitation of bottom sediments, which in turn can result in the release of pollutants and nutrients.	Disturbance of the structure of the seabed; Release of pollutants and nutrients from bottom sediments; Sedimentation of agitated sediments.	NO
D6. Seabed integrity	GES	Installing foundations, burying	Disturbance of the structure of the seabed;	NO

Feature-Descriptive Indicator/Place of Analysis in Report	Current status of the Bornholm Basin basin	Link to the Project	Potential impacts	Assessment of the impact of the Project on environmental objectives [affects - YES/does not affect - NO]
Chapters: TIV: R 2, R 3.		cables and making embankments of rock material will lead to occupation of the seabed and locally lead to changes in the environmental conditions of the seabed.	Release of pollutants and nutrients from bottom sediments; Sedimentation of agitated sediments; Presence of steel/concrete structures and cables.	
D7. Hydrographic conditions Chapter: TIV: R 2.	GES	Temporal dispersion of agitated material from the seafloor. Presence of steel/concrete structures and cables, and occupation of space during construction work.	Bottom sediment agitation; Changes in hydrodynamic conditions.	NO
D8. Pollutants and their effects Chapters: TIV: R 2, R 3, R 4.	GES (in the D8C2 and D8C3 GES criteria group, subGES for the D8C1 criteria group)	Construction work, including installation of foundations and cables, making rock embankments, anchoring, etc. will cause temporary agitation of bottom sediments. Release of metals from anodes.	Disturbance of the structure of the seabed; Release of pollutants and nutrients from bottom sediments; Anode emissions.	NO
D9. Contaminants in fish and shellfish for consumption Chapters: TIV: R 2, R 3, R 4.	GES (GES for 9 substances, subGES for the sum of PBDE congeners)	Construction work such as installing foundations and cables and making rock embankments, anchoring, etc. will cause temporary agitation of bottom sediments.	Disturbance of the structure of the seabed; Release of pollutants and nutrients from bottom sediments; Anode emissions.	NO

Feature-Descriptive Indicator/Place of Analysis in Report	Current status of the Bornholm Basin basin	Link to the Project	Potential impacts	Assessment of the impact of the Project on environmental objectives [affects - YES/does not affect - NO]
		Release of metals from anodes.		
D10. Waste in the marine environment Chapters: not applicable	lack of data	Due to the need for waste management on land, project activities will not be relevant.	None - not applicable.	NO
D11. Underwater noise Chapters: TIV: R 4, R 6.	subGES	The impacted area may contain species sensitive to underwater noise (marine mammals, fish).	Underwater noise associated with foundation installation.	NO

According to the 2013 Preliminary Assessment of the Environmental Status of Marine Waters, the overall assessment of Polish marine waters was determined to be below good status (subGES). On the other hand, the assessment on a sub-basin-by-sub-basin basis showed good status (GES) as achieved only for basin 36 - open waters of the Bornholm Basin. The update of the preliminary assessment of the environmental status of the Polish Baltic Sea zone was carried out using a modified methodology, which makes it impossible to unambiguously compare the results of the updated assessment with the preliminary assessment, nevertheless, thanks to this change, it is possible to maintain compatibility of the assessment methods adopted in the Baltic Sea region. The updated preliminary assessment also does not include a feature-based overall assessment for Polish marine waters and individual basins.

4.3. Baltic Sea Action Plan HELCOM

- Achievement of the good ecological status of the Baltic environment is assessed according to criteria established for four key intervention sectors:
  - eutrophication - the goal is to achieve a state in which the Baltic Sea is not affected by eutrophication, and the determinant of this state is the achievement of operational ecological goals:
  - nutrient concentrations close to natural levels;
  - clear water;
  - algae blooms at natural levels;

  - the natural occurrence and distribution of plants and animals;
  - the natural oxygenation level of the waters;
- hazardous substances - the goal is to achieve such a state of the Baltic Sea, when the lives of organisms will not be threatened by the presence of hazardous substances. The operational environmental goals are:
  - concentrations of hazardous substances slightly different from natural ones;
  - all fish useful for consumption;
  - no health problems in animals;
  - radioactive contamination at pre-Chernobyl levels;
- biodiversity and nature conservation - the strategic objective is to achieve a favorable conservation status of the Baltic Sea biodiversity, the operational objectives to achieve this objective are:
  - restoration and maintenance of the integrity of the seabed at a level that guarantees the functioning of ecosystems;
  - demonstration by habitats and associated species of distribution, abundance and quality in accordance with prevailing physiographic, geographic and climatic conditions;
  - water quality adequate to ensure the integrity, structure and functioning of the ecosystem to be restored or preserved;
- offshore operations - the strategic objective in this segment is to conduct marine transportation and other offshore activities in a manner that is friendly to the marine environment, its achievement is to be served by operational management objectives:
  - prohibition of illegal discharges - as compliance with already existing international regulations;
  - safe maritime transportation without pollution incidents;
  - an effective rescue and accident response service equipped with adequate rescue capabilities;
  - minimizing pollution from ship sewage;
  - no case of introduction of alien species from ships;
  - minimizing atmospheric pollution from ships;
  - no harmful discharges from offshore mining platforms;
  - minimizing the risks associated with offshore structures.

The strategic and operational goals are binding for the Baltic Sea as a whole, with analyses of the status and progress in achieving the goals being conducted for the sub-accessions. From the point of view of the Project's area of influence, the Borholm Basin subacre is important.

According to the state assessment conducted as part of Helcom's second comprehensive assessment of the state of the Baltic Sea (State of the Baltic Sea - Second HELCOM holistic assessment 2011-2016) - the result for the Borholm Basin sub-acreage is a failure to achieve good ecological status. Also, the evaluation of sub-measures indicates the lack of attainment of good status in each component category. As can be seen from the impact assessment carried out (see Volume IV of the EIA), the proposed changes to the project previously assessed will not affect the nature and extent of the impacts potentially generated by the implementation of the project in its original form, and thus this allows us to conclude that the Project will not significantly alter the ecological status in any of the listed component categories.

Environmental Decision	Decision on environmental conditions issued by the Regional Director for Environmental Protection in Gdańsk on July 7, 2016, ref. No. RDOŚ-Gd-WOO.4211.12.2015.KP.22, for the project named "Construction of the Bałtyk III Offshore Wind Farm"
DWA	Decision on environmental conditions for the implementation of the project
KPA	act of June 14, 1960 Code of Administrative Procedure (i.e. OJ. U. of 2021, item 735, as amended).
OWF BIII/ Project	Offshore wind farm OWF Bałtyk II (originally: Bałtyk Środkowy III and Polenergia Bałtyk III)
EIA	Environmental Impact Assessment
PSZW	Permit for the erection and use of artificial islands, structures and devices in Polish maritime areas
Report 2015	Environmental impact assessment report for the proceedings completed by the decision of RDOŚ dated July 7, 2016, mark: RDOS-Gd-WOO.4211.12.2015.KSZ.22
Report/EIA Report	Environmental Impact Assessment Report for the amendment to the decision on environmental conditions issued for the Bałtyk Środkowy III OWF
RDEP	Regional Director of Environmental Protection in Gdansk
EIA Act	Act of October 3, 2008 on access to information on the environment and its protection, public participation in environmental protection and on environmental impact assessments(consolidated text, Journal of Laws of 2022, item 1029).

1. Introduction

This Section describes the legal requirements for the environmental impact assessment procedure in procedural terms, as well as determining the scope of the EIA Report with particular attention to the specifics of the procedure involving the amendment of the decision on environmental conditions

EIA is carried out in Poland under the provisions of the Act of October 3, 2008 on providing information about the environment and its protection, public participation in environmental protection and environmental impact assessments. This law, together with implementing regulations, in particular the Decree of the Council of Ministers of September 10, 2019 on projects likely to have a significant impact on the environment, fully implements the provisions of Directive 2011/92/EU of the European Parliament and of the Council of December 13, 2011 on the assessment of the effects of certain public and private projects on the environment (the "EIA Directive"), hence there is no need to separately describe the requirements of this Directive in the report.

It should be mentioned that the procedure for amending the DWA, as well as the legal requirements, are analogous to those for the issuance of this decision with the proviso that they should be taken into account to the extent corresponding to the subject and nature of the changes planned to be made.

2. The scope of the EIA Report and its compliance with the requirements of the of the law

This Environmental Impact Report was prepared for the purpose of amending the environmental decision dated July 7, 2016, mark: RDOS-Gd-WOO.4211.12.2015.KSZ.22 issued by the Regional Director of Environmental Protection in Gdansk ("Environmental Decision"). The scope of the EIA Report was adapted to the subject matter and scope of the changes covered by the application. The information presented in the Report refers to the current conditions related to the implementation of the planned Project, which, according to the proposal of the project planner, are to be determined differently than in the aforementioned decision. In addition, the Report presents the environmental effects of its implementation in areas where the planned changes result in a consequent need to update the conditions for implementation of the project in relation to those presented in the EIA Report prepared at the stage of issuing the Environmental Decision (the "2015 Report").

Formally, the scope of the environmental impact report is defined in Article 66 of the UoA. In the case of the EIA Report, prepared for the purpose of making changes to the Project implemented through an amendment to the Decision, its scope is analogous. However, bearing in mind that the changes made do not result in changes to all the conditions presented in the 2015 Report, this Report refers to the 2015 Report in terms of information that remains current, due to the fact that in this regard the provisions of the environmental decision of July 7, 2016 also remain current and are not subject to change.

Below is a table that presents the scope of the report under the law and its reference to the scope of this EIA Report for the amendment of the Environmental Decision issued for the BIII OWF and the 2015 Report in case the information contained therein remains valid. This summary allows to systematize the document indicating its compliance with the provisions of the EIA Act.

Requirements of Article 66 of the UoA - the report should include:	Relevant section of the IMF BIII report
1) a description of the planned project, in particular: • specification of the investment as a whole and land use conditions at the stage of construction and operation or use, • key specific features of the production processes, • anticipated types and amounts of pollution, resulting from the operation of the planned project;	• Volume II, Sections 1, 3 - 6, 8 - 13 • chapter 3 in each of the Sections of Volume IV (only the basic parameters needed to assess a given environmental element) • Volume V, Section 2
2) description of natural elements of the environment covered by the scope of the anticipated impact of the planned project on the environment, including elements of the environment protected under the Act of April 16, 2004 on nature protection;	• Volume III, Sections 2 - 14 • chapter 8 in each Section of Volume IV (description limited to environmental resources/species subject to EIA)
3) description of existing monuments in the vicinity or within the direct range of influence of the planned project protected under the provisions on the protection and care of monuments;	• Volume III, Section 12
3a) description of the landscape in which the project is to be located	• Volume IV, Section 9
3b) information on connections with other projects, in particular on accumulation of impacts of ongoing, completed or planned projects, for which a decision on environmental conditions was issued, located in the area where the project is planned to be implemented, and in the area of impact of the project or whose impacts fall within the area of impact of the planned project - to the extent to which their impacts may lead to accumulation of impacts with the planned project;	• Volume II, Section
4) a description of the anticipated effects on the environment if the project is not undertaken;	• Volume IV, Sections 2 - 11 (Chapter 5 in each Section of Volume IV)
5) a description of the options analyzed, including: • scenario proposed by the application and reasonable alternative scenario, • the variant that is most favorable to the environment, along with the reasons for their selection;	• Volume II, Section 2

Requirements of Article 66 of the UoA - the report should include:	Relevant section of the IMF BIII report
6) determination of the anticipated environmental impact of the analyzed variants, including in the event of a major industrial accident, as well as possible transboundary environmental impact, and in the case of a road in the trans-European road network, determination also of the impact of the planned road on road safety;	• Volume IV, Sections 2 - 14 (Chapters 9 - 11, 13 in each Section of Volume IV)
6a) comparison of the impacts of the analyzed alternatives	• Volume IV, in each Evaluation Section of Volume IV
7) justification of the variant proposed by the applicant, indicating its impact on the environment, in particular on: • humans, plants, animals, fungi and natural habitats, water and air, • land surface, with consideration to ground mass movements, climate and landscape, • tangible assets, • monuments and cultural landscape, covered by existing documentation, in particular, a register or record of monuments, • forms of nature protection, including on the goals and objects of protection of Natura 2000 areas, as well as the continuity of ecological corridors connecting them • the interaction between the elements mentioned above (as defined in paragraphs a-f of the EIA Act)	• Volume II, Section 2 • Volume IV, Sections 2 - 11 (Chapters 9 - 14 in each Section of Volume IV)
8) a description of the forecasting methods used by the applicant and a description of the anticipated significant environmental impacts of the planned project, including direct, indirect, secondary, cumulative, short-, medium- and long-term, permanent and temporary environmental impacts resulting from: • existence of the venture, • use of environmental resources, emissions;	• Volume IV, Sections 1 - 14 (Chapter 6 in each Section of Volume IV)
9) a description of the actions envisaged to prevent, limit or compensate for negative environmental impacts, in particular on the objectives and object of protection of the Natura 2000 area and the integrity of the area;	• Volume IV , Sections 2 - 7 (Chapter 12 in each Section of Volume IV) • Volume V, Sections 3 - 7
10) a - not applicable	• Not applicable

Requirements of Article 66 of the UoA - the report should include:	Relevant section of the IMF BIII report
10) b - not applicable	• Not applicable
11) if the planned project is related to the use of installations, a comparison of the proposed technology with a technology that meets the requirements referred to in Article 143 of the Act of April 27, 2001. - Environmental Protection Law;	• Volume V, Section 14
11a) reference to environmental objectives arising from strategic documents relevant to the implementation of the project;	• Volume I, Section 2
12) indication whether it is necessary for the planned project to establish a limited use area within the meaning of the provisions of the Act of April 27, 2001. - Environmental Protection Law, and determination of the boundaries of such an area, restrictions on land use, technical requirements for construction facilities and ways of using them; this does not apply to projects involving the construction of a national road;	• Volume V, Section 10
13) presentation of issues in graphic form;	• Entire report
14) presentation of issues in cartographic form at a scale that corresponds to the subject matter and detail of the issues analyzed in the report, and that allows for a comprehensive presentation of the conducted analysis of the environmental impact of the project;	• Entire report
15) analysis of possible social conflicts related to the planned project;	• Volume IV, Section 11
16) presentation of proposals for monitoring the impact of the planned project at the stage of its construction and operation or use, in particular on the objectives and subject of protection of the Natura 2000 area and the integrity of the area;	• Volume IV, Sections 1 - 11 (Chapter 14 in each Section of Volume IV) • Volume V, Section 9
17) indication of difficulties arising from shortcomings in technology or gaps in modern knowledge that were encountered in the preparation of the report;	• Volume IV, Sections 1 - 11 (Chapter 16 in each Section of Volume IV) • Volume V, Section 15

Requirements of Article 66 of the UoA - the report should include:	Relevant section of the IMF BIII report
18) a summary in non-specialist language of the information contained in the report, for each element of the report;	• Volume VI
19) the name of the person or persons preparing the report;	• Volume I, Section 1, Chapter 4 • Volume III, Sections 2 - 14
19a) a statement by the head of the team of authors of the team, on compliance with the requirements,	• Appendix to the Report
20) 20) Sources of information underlying the report	• Sources of information are indicated at the end of each Section of the report
The information referred to in paragraph 1 points 4-8 should take into account the anticipated impact of the analyzed variants on the objectives and object of protection of the Natura 2000 area and the integrity of the area.	• Volume IV, Chapter 12 in each of the Sections of Volume IV
If the possibility of a transboundary environmental impact is identified, the information referred to in paragraph 1 items 1-16 should take into account the determination of the impact of the planned project outside the territory of the Republic of Poland.	• Volume IV, Chapter 13 in each of the Sections of Volume IV • Volume V, Section 7
If it is necessary for the planned project to establish a limited use area, the report should be accompanied by a copy of the cadastral map certified by the competent authority with the course of the boundaries of the area where it is necessary to establish a limited use area. This does not apply to projects involving the construction of a national road.	• Volume V, Section 10
The report on the environmental impact of the project should consider the impact of the project at the stages of its implementation, operation or use, and decommissioning.	• Volume IV, Sections 2 - 11, (Chapter 9 in each Section of Volume IV)

3. Qualification of the project for EIA

The subject of the proceedings for the purpose of which the EIA Report was prepared is the amendment of the conditions for a project classified as one that may always have a significant impact on the environment, being the construction of the BIII offshore wind farm, which has received a valid

and final decision of the RDOŚ on environmental conditions dated July 7, 2016, which involves the construction of an installation using wind energy to generate electricity, located in the maritime areas of the Republic of Poland.

Taking into account the current state of the law, the intention is listed in the Decree of the Council of Ministers of September 10, 2019 on projects that may significantly affect the environment (Journal of Laws of 2019, item 1839) in § 2 paragraph 1 item. 5) b):

installations using wind energy for electricity generation located in the maritime areas of the Republic of Poland.

At the time when the RDOŚ issued the environmental decision of July 7, 2016 for the BIII OWF, the Regulation of the Council of Ministers of November 9, 2010 on projects that may significantly affect the environment was in force (i.e., Dz. U of 2016, item 71), according to which it was among the projects likely to always have a significant impact on the environment listed in § 2 (1) item. 5) of the aforementioned regulation:

installations using wind energy for electricity generation with a total nominal capacity of the plant of not less than 100 MW and located in the maritime areas of the Republic of Poland.

The circumstance related to the change in the legal status regarding the classification of projects as likely to have a significant impact on the environment does not affect the ability of the authority to amend the DWA.

For the purposes of this proceeding to amend the decision on environmental conditions, the legal basis for conducting the proceedings and preparing this EIA Report will be Article 87 of the EIA Law, which states that: "The provisions of this section and Section VI shall apply mutatis mutandis in the event of a change in the environmental decision. The provision of Article 155 of the Code of Administrative Procedure shall apply mutatis mutandis, with the proviso that consent shall be given only by the party that applied for the environmental decision, or the entity to which the environmental decision was transferred."

According to Article 155 of the Code of Administrative Procedure Act, "A final decision, by virtue of which a party has acquired a right, may be at any time with the consent of the party annulled or modified by the public administration body that issued it, if special provisions do not oppose the annulment or modification of such decision and the public interest or the legitimate interest of the party supports it; the provision of Article 154 § 2 shall apply accordingly." Bearing in mind that the BIII offshore wind farm is among the projects that may always have a significant impact on the environment, listed in § 2 Section 1 item. 5) b) of the Decree of the Council of Ministers on September 10, 2019 on projects likely to have a significant impact on the environment, if the decision on environmental conditions is amended, it is necessary to conduct an environmental impact assessment procedure and prepare an environmental impact report.

At the same time, it should be emphasized that the proposed amendment to the Environmental Decision is not opposed by any legal provision, nor does the amendment itself lead to a violation of the public interest. The social interest that the decision on environmental conditions realizes is expressed in the assessment of the possibility of realization of the planned project in a given location and such determination of the conditions for its implementation as to minimize the possibility of

negative effects on people and the environment associated with the implementation and operation of the Project. The proposed change to the terms of the Environmental Decision does not in any way lead to a reduction in the level of protection of people and the environment established by the existing content of the decision - as demonstrated in the body of the Report. This change is possible precisely as a result of the modification of the parameters of the Project, including in connection with taking into account already at this stage some of the recommendations and conditions specified in the Environmental Decision, as well as changes in the available parameters of offshore wind turbines that occurred during the preparation of the project for implementation. And, in particular, it should be pointed out that the impact assessment carried out in this Report has a dimension and effect equivalent to the environmental reassessment, and thus the purpose of imposing the reassessment as specified in the text of the Environmental Decision will be achieved.

4. Course of proceedings EIA

According to Article 3 (1) (8) of the EIA Act, the environmental impact assessment of a project is understood as the proceedings on the environmental impact assessment of the planned project, including in particular:

a. verification of the project's environmental impact report,
b. obtaining the opinions and agreements required by law,
c. providing opportunities for public participation in the proceedings.

The BIII offshore wind farm is among the projects that may always have a significant impact on the environment, for which an EIA was mandatory. Environmental impact assessment proceedings will also require amending the terms of the environmental conditions decision, which was issued by the RDOŚ for the implementation of the BIII OWF.

EIA in the case of a change in the decision on environmental conditions is carried out as part of the administrative proceedings conducted on a change in the decision on environmental conditions under the procedural rules as for projects that may always have a significant impact on the environment, or for projects that may potentially have a significant impact on the environment in the event that such an obligation was determined by the authority competent to issue the decision on the basis of the so-called screening order.

In the case of the project in question and the changes introduced in the DŚU that has been issued for it, the proceedings will be conducted in accordance with the rules in force for projects that may always have a significant impact on the environment, i.e. it will be required to: prepare an environmental impact report, ensure public participation and obtain the required agreements and opinions. The legal basis for issuing a decision amending the DWA will be Article 87 of the EIA Law in conjunction with Article 155 of the CAP.

The environmental assessment procedure conducted for the purpose of amending the EIA in the present case therefore consists of the following stages:

1. documentation preparation,
2. submission of a DSU application, along with an EIA report,
3. analysis of the documentation by the body conducting the proceedings, the consulting body and the consensus body,

4. issuance of an opinion/agreement,
5. public consultation,
6. issuance of an adjudication.

The preparation of the documentation for obtaining the DWA, as well as for amending this decision for the BIII offshore wind farm, was preceded by the necessary analyses of technical conditions, as well as, most importantly, environmental conditions. The basis for this Report was the EIA Report prepared for the proceedings concluded by the RDEP, which issued the amended decision on environmental conditions. Other projects planned for implementation in the vicinity of the BIII OWF site were also considered. Since the issuance of the Environmental Decision for the OWF Bałtyk Środkowy III, progress has been made in the knowledge of natural resources in Polish maritime areas, of other investments of this type planned in the vicinity of the Project, and the Project itself is at a much more advanced stage of development, as well as the parameters of available offshore wind power plants have changed. The consequence of the development of other offshore wind farm projects is a significant change in the factual conditions, including as a consequence of the obligations imposed in the content of the issued decisions on environmental conditions, and which constitute the implementation environment of the Baltic Central Sea III OWF. In the issued decisions on environmental conditions, the environmental protection authorities determined the shape and location of corridors ensuring undisturbed migration of birds to Slupsk Shoal, validated a significant part of the statements on the potential impacts of other offshore wind farm projects planned in Polish maritime areas, including the cumulative impacts of these projects and the Project, and verified a number of solutions for the proposed minimization measures. In particular, it is important to emphasize the development work on the OWF Central Baltic III project itself, which has been going on since the date of issuance of the Environmental Decision, i.e. since July 2016. Since then, wind measurements have been taken, preliminary geotechnical studies have been carried out and the boundary conditions defined by the Environmental Decision have been used to prepare a plan for the deployment of the farm's infrastructure and preliminary verification of possible technologies to be used.

Based on information from the above sources and the requirements of Article 66 of the UoA, this report has been prepared. An application for a DWA has also been prepared.

The preparation of the Report was preceded by an analysis of the EIA Report prepared prior to the issuance of the Environmental Decision, and consequently also by environmental studies necessary to analyze the conditions and environmental impact of the changes planned to be implemented under the application and

this EIA Report. With regard to the technical conditions of the project and the environmental conditions, which are not subject to change, the results of the marine environment studies conducted for the implementation of the BIII OWF were used. Preparing the Report also used the results of studies conducted for other OWFs being prepared for implementation in the northeastern slope of Slupsk Shoal, as well as analyses dedicated to the changes being made. Attached to the EIA Report is the methodology that forms the basis for the assessment conducted as part of this EIA Report (Volume III).

The application for a decision amending the DWA issued for the BIII OWF is submitted to the authority that issued the environmental decision to be amended, i.e. RDOŚ in Gdańsk, which was competent to

issue a decision on environmental conditions in accordance with Article 75 (1)(1)(c) of the EIA Act.

The EIA report (3 copies) and a graphic appendix showing the extent of the Project's impact are attached to the application to amend the EIA. The application does not include a cadastral map, extracts from the land register, and extracts from the local zoning plan, as the Project is implemented in marine areas. The planned Project is in accordance with the Spatial Development Plan for the Polish maritime areas of internal waters, territorial sea and exclusive economic zone at a scale of 1:200000.[1] The project is planned for implementation in the POM.45.E area, which is designated in the Plan for renewable energy generation, while internal and external technical infrastructure are considered integral to projects of this type. The plan takes into account the permit for the erection and use of artificial islands, structures and devices in Polish maritime areas issued to the Investor for the subject body of water with the reference GI7/62/1170069/Decision/2012 by the Minister of Transport, Construction and Maritime Economy on March 30, 2012.

The RDOŚ in Gdansk sends the received documentation (consistent with the scope as described above), together with an application for an opinion, to the State Border Sanitary Inspector in Gdynia (Art. 77 par. 1 pt. 2 and Art. 78 par. 1 pt. 2 of the EIA Act), and with an application for agreement on the conditions for the implementation of the project - to the Director of the Maritime Office in Gdynia (Art. 77 par. 1 pt. 1 of the EIA Act).

The application and the report are reviewed by the authority conducting the proceedings, the consulting authority and the concurring authority. Pursuant to Article 77(6) of the UoA, the Director of the Maritime Office and the State Border Sanitary Inspector have 30 days to issue an agreement or opinion, respectively. The EIA Act does not set a deadline for the issuance of a DSU, however, in the case of offshore wind farms, specific solutions have been introduced, according to which decisions on environmental conditions for investments consisting in the construction and maintenance of offshore wind farms are issued within 90 days from the date of submission of the application - the provision of Article 76(2) in connection with the provision of Article 76(1)(1) of the Act of December 17, 2020 on promoting electricity generation in offshore wind farms (Journal of Laws of 2021, item 234, as amended).

After analyzing the application and the report, the Director of the Maritime Office in Gdynia issues a decision agreeing to the conditions for the implementation of the project, or refuses such agreement. In turn, the State Border Sanitary Inspector issues an opinion on the matter. The parties are not entitled to complain about any of the aforementioned provisions.

Prior to the issuance of the EIA, in accordance with the provision of Article 79 (1) of the EIA Act, a public participation procedure (the so-called public consultation) will be carried out, during which everyone has the right to review the project documentation and submit comments and proposals.

The final part of the proceedings is the issuance of an environmental decision or refusal to issue one (also in the form of a decision).

Parties to the proceedings or entities acting as parties, dissatisfied with the decision, have the right to appeal the decision to the General Director of Environmental Protection. An appeal shall be filed within fourteen days from the date of delivery of the decision to a party, or within 30 days from the

[1] Ordinance of the Council of Ministers of April 14, 2021 on the adoption of a spatial development plan for internal marine waters, territorial sea and exclusive economic zone at a scale of 1:200,000 (Journal of Laws of 2021, item 935)

date of announcement or delivery of a notice of decision issuance - the provision of Article 76(5) in conjunction with the provision of Article 76(1)(1) of the Law of December 17, 2020 on the Promotion of Electricity Generation in Offshore Wind Farms. An appeal against an environmental decision issued for an offshore wind farm must contain objections relating to the decision, specify the essence and scope of the demand that is the subject of the appeal, and indicate evidence justifying the demand, while the appeal should be considered within 60 days from the date of its receipt - the provisions of Article 76 (4) and (5) of the Law of December 17, 2020 on Promoting Electricity Generation at Offshore Wind Farms.

Environmental Decision	Decision on environmental conditions issued by the Regional Director for Environmental Protection in Gdańsk on July 7, 2016, ref. No. RDOŚ-Gd-WOO.4211.12.2015.KP.22, for the project named "Construction of the Bałtyk III Offshore Wind Farm"
DWA	Decision on environmental conditions for the implementation of the project
KPA	act of June 14, 1960 Code of Administrative Procedure (i.e. OJ. U. of 2021, item 735, as amended).
OWF BIII/ Project	Bałtyk Środkowy III Offshore Wind Farm
EIA	Environmental impact assessment
Report 2015	Environmental impact assessment report for the proceedings completed by the decision of RDOŚ dated July 7, 2016, mark: RDOS- Gd-WOO.4211.12.2015.KSZ.22
Report/EIA Report	Environmental Impact Assessment Report for the amendment to the decision on environmental conditions issued for the Bałtyk Środkowy III OWF
RDEP	Regional Director of Environmental Protection in Gdansk
EIA Act	Act of October 3, 2008 on access to information on the environment and its protection, public participation in environmental protection and on environmental impact assessments(consolidated text, Journal of Laws of 2022, item 1029).

1. Introduction

One element that is particularly important in the environmental impact assessment procedure is public participation, as required by the EIA. This procedure is commonly referred to as public consultation. In accordance with the general principle expressed in Article 79(1) of the EIA Law, it is mandatory to ensure public participation in the proceedings in which the environmental impact assessment of a project is carried out, before issuing an EIA. Based on these regulations, any interested party has, among other things, the right to review the project documentation and submit comments and proposals. Other elements of public participation envisaged by the law include the opportunity for the public to be informed about key issues related to the procedure and the activities undertaken as part of it, and, most importantly, about the decision made and the opportunity to learn about its content.

Within the framework of public participation in the environmental impact assessment procedure, the documentation of the proceedings, i.e. primarily the environmental impact report document and opinions or agreements, if available, are made available to the public. The designated period for submitting comments and proposals is 30 days. According to the law, comments and applications submitted after the 30-day deadline are left without consideration.

In the case of an amendment to the decision on environmental conditions, as stipulated in Article 87 of the UoA, the obligation to ensure public participation in this procedure should be carried out on principles analogous to the procedure for issuing a decision on environmental conditions.

2. Formal consultation procedure public

2.1. Contents of the notice of consultation public

The manifestation of public participation is the provision of information to the extent specified in the law, which presents data on the key stages of the proceedings, as well as, in response to such information, allows the interested public to take actions to which they are entitled or which may be crucial to them in terms of being able to acquire adequate knowledge of the planned project.

One such key element of the procedure, to which the obligation to notify the public corresponds, is the so-called public consultations, which include, within their scope, the display for review of the documentation prepared for this procedure, in particular the environmental impact report. Referring to the public consultation notice, it should include information on:

1) to proceed with an environmental impact assessment of the project;
2) subject of the decision to be issued in the case;
3) the authority competent to issue a decision and the authorities competent to issue opinions and make arrangements;
4) opportunities to familiarize themselves with the necessary case documentation and the place where it is on display for inspection;
5) the opportunity to submit comments and proposals;
6) how and where to submit comments and proposals, while indicating the 30-day deadline for their submission;
7) the authority competent to consider comments and applications.

The other data that is subject to public disclosure is information on:

1) initiation of proceedings;

2) the date and place of the administrative hearing open to the public referred to in Article 36, if it is to be held;

3) transboundary environmental impact proceedings, if conducted.

As for the information on the initiation of proceedings, as a rule, it is provided at the very beginning of the proceedings immediately after their initiation in the form of a separate notice.

2.2. Form of public disclosure public

Ensuring public participation by providing information to the interested public, within the scope of Article 33 (1) of the EIA Law, takes the form of public disclosure.

According to Art. 3 pt. 11) of the EIA Act, making information public is understood as:

a) making the information available on the website of the Public Information Bulletin, the competent authority in the case;
b) announcement of information, in a customary manner, at the headquarters of the authority having jurisdiction over the case;
c) announcement of information by public notice in a customary manner in the place of the planned project;
d) where the seat of the authority with jurisdiction over the case is located in a municipality other than the municipality with jurisdiction over the subject matter of the proceedings - also by announcement in the press or in the customary manner in the locality or localities with jurisdiction over the subject matter of the proceedings.

Public disclosure, according to established case law, is effective the moment it is made. This means that the deadlines that depend on public disclosure begin to run from the moment this action is taken, e.g., the 30-day period for reviewing the necessary case documentation and for submitting comments and proposals.

2.3. Necessary documentation matters

The EIA Law, in Article 33(2), includes among the necessary case documentation:

1) an application for a decision or an amendment thereto, together with the required attachments;
2) required by regulations:
   a) the decision of the authority competent to issue the decision,
   b) positions of other bodies, if the positions are available by the deadline for submission of comments and proposals.

These documents are subject to access by the interested public throughout the entire period of the proceedings, but beyond the 30-day filing period, this is done at the request of the interested party, which is carried out for non-parties to the proceedings under the procedure for access to environmental information.

2.4. Comments and conclusions

Comments and motions are the form in which the interested public can comment on the environmental impact report prepared for the proceedings and the procedure itself for which it was prepared.

Comments and applications may be submitted by the deadline specified in the notice of public disclosure. The notice also indicates the place where the documentation put out for public consultation can be consulted, as well as the place and manner in which comments and proposals can be submitted as part of the proceedings.

According to the EIA Law, comments can be submitted:

1) orally for the record,

2) in writing;

3) by means of electronic communication systems without the need for a qualified electronic signature.

According to Article 35 of the EIA Law, comments submitted after the deadline are left without consideration. The body issuing the decision on environmental conditions is obliged to refer to the comments and requests submitted in a correct manner in the justification to the issued decision, indicating how they were taken into account.

3. Source materials and comparative

3.1. Acts legislation

1. Act of June 14, 1960 Administrative Procedure Code (i.e. OJ. U. of 2021, item 735, as amended).

Disorders	Any interference with the environment caused by the project, which may cause changes in the functioning of the ecosystem (both negative and positive), not being emissions

1. Introduction

This chapter presents a description of the methodology that was used to perform an environmental impact assessment for changes to the Central BIII OWF, for which an environmental decision was previously issued. The chapter also presents a diagram of the entire EIA Report, along with information on which elements of the assessment are presented in each volume of the study.

The subject of this Report, as well as the environmental impact assessment conducted herein, is not the Central BIII OWF project. This document is prepared for the purposes of the proceedings conducted in accordance with Article 87 of the EIA Act in conjunction with Article 155 of the Kpa, and thus it concerts the changes planned to be made to the BIII OWF project, and consequently the modifications that must be implemented in the decision on environmental conditions for the planned changes to the BIII OWF to take place. This nature of the procedure for amending the decision on environmental conditions also significantly affects the methodology for conducting the environmental impact assessment - about which in the following chapters, no less, the structure and a significant part of the methodological assumptions are repeated after the environmental impact report prepared for the procedure on the decision on environmental conditions, which ended with the issuance by the Regional Director of Environmental Protection in Gdansk on July 7, 2016 of a decision on environmental conditions, marked RDOŚ-Gd-WOO.4211.12.2015.KSZ.22, for the project entitled. "Construction of the offshore wind farm Baltic Central III". Maintaining the internal structure of the environmental impact report analogous to that of the environmental impact report forming the basis for obtaining the Environmental Decision is intended to make it possible to ensure the conditions of comparability of the material forming the basis for issuing the Environmental Decision and the current amendment process. The question of the assessment methodology is slightly different, which is due to the nature of the procedure for amending the decision on environmental conditions, but nevertheless the methodology used in the environmental impact report forming the basis for the Environmental Decision has been recycled as much as possible.

This chapter also fulfills the requirements of Article 66 (1) (8) of the EIA, according to which the report on the impact of the project should include a description of the forecasting methods used by the applicant.

The presentation in Volume I of the Report of its outline, along with an explanation of the role and content of its various parts, is intended to facilitate the analysis of this extensive study and increase the efficiency of the impact assessment of the Project's changes to the parameters approved in the Environmental Decision proposed in this Report, taking into account the specifics of the procedure for amending the Environmental Decision.

2. General scheme of assessment impact

This EIA Report is a document that describes all of the work, as well as all of the results of the research and analysis, used to assess the environmental impact of the proposed changes to the Project within the parameters approved in the Environmental Decision.

The main assumption of the assessment concept used was to determine how the parameters of the BIII offshore wind farm, and possibly the methods of its implementation or subsequent operation, which are proposed to be changed as a result of the proceedings to amend the Environmental Decision, affect

the nature, extent and intensity of the impacts caused by the implementation and operation of the BIII offshore wind farm.

The methodology for conducting an impact assessment must be tailored to the specifics of the proceedings under which it is conducted. In the case at hand, two features significantly affect the specifics of the environmental assessment being conducted. The first is due to the very nature of the proceedings, which is the amendment of the environmental decision. In such a case, the subject of the proceedings is not the impacts caused by the project itself, as these have already been assessed, but the consequences that the assessed impacts are related to the introduction of modifications to the project, for which the decision on environmental conditions has already been issued. Theoretically, the result of evaluating planned modifications for an already approved project could be threefold. First, the modifications may leave the nature of the impacts generated, their extent and the magnitude of the impacts unaffected. The impacts caused by the project under the modified parameters may be less in terms of the scope and magnitude of the impacts caused than those assessed for the project that is being modified. The third situation is when the planned changes to the project for which the environmental decision was issued cause the scope or magnitude of the impacts to increase, or alternatively change their nature.

The first two cases, i.e., the lack of impact of modifying the parameters of the project on impacts or the impact consisting of a reduction in their scope or magnitude, means that the impacts of the project after the proposed modification will not affect the environment in additional ways that have not yet been assessed. Thus, from the point of view of the purpose of conducting an environmental impact assessment for an amendment to an environmental decision, i.e. assessing the permissibility of modifying the parameters of a project, it is sufficient to confirm that modifying the parameters of a project does not affect the nature, scope and magnitude of impacts, without the need to give a precise measure of the change in impact.

Another situation concerns the third case, i.e., when modification of the parameters of the project affects the scope or magnitude of the generated impacts or their nature in such a way that they are increased or new, previously unassessed impacts appear. In such a case, the impact assessment of the project subject to the proposed modification should make it possible to assess the degree and nature of the change in impact or determine the significance of the overall type of changed environmental impact.

The second important feature affecting the specificity of the conducted environmental impact assessment is the manner/methodology of conducting the environmental impact assessment in the course of the proceedings under which the Environmental Decision was obtained - the original impact assessment. This assessment was carried out based on the concept of the envelope, i.e., determining the parameters of the project that generate the most far-reaching impacts of the so-called "far-reaching scenario" (NIS) and subjecting such theoretical shape of the project to an impact assessment. The furthest-reaching scenario then provides a benchmark for assessing whether the planned project as proposed for implementation is acceptable, or alternatively, what conditions must be introduced for the furthest-reaching scenario so that the impacts generated by the project are not significantly negative impacts. These verified and limited to the thresholds of safe and environmentally acceptable conditions for the implementation of the Project were specified by the authority in the Environmental Decision. Thus, the conditions set forth in the Environmental Decision have become the most far-reaching scenario of acceptable impacts of the Project. In each case, it is the conditions set forth in the

Environmental Decision that are the benchmark for evaluating the changes proposed in this proceeding. Indeed, as noted above, the purpose of this assessment is to verify whether a change in the parameters of the Project made at a further stage of project development, as well as a requested amendment to the Environmental Decision, may cause different or of a different magnitude of environmental impacts than those specified in the Decision. Nonetheless, since the impact assessment contained in the 2015 Report is based on an assessment of the impact of the parameters that may cause the most far-reaching impact scenarios (NIS), in conducting this impact assessment of the proposed amendments to the Environmental Decision and the concretization of the parameters of the Project, it is necessary not only to refer to the conditions specified in the Environmental Decision, but also to the most far-reaching scenario adopted in the 2015 Report (NIS 2015). Indeed, if it was the 2015 NIS that was the basis for conducting the assessment of individual impacts in the course of the original impact assessment of the Project, then only a comparison with the NIS provides a real basis for concluding that the impacts currently under consideration do not exceed the scope of the impact assessment conducted to date, which was the basis for the issuance of the amended Environmental Decision. Thus, in conducting the impact assessment in this Report, reference was made both to the conditions for implementation and operation of the Project approved by the Environmental Decision as a reference point for the proposed modifications to the content of the Environmental Decision, as well as reference was made to the 2015 NIS for reference to the environmental assessment performed in the 2015 Report.

Thus, the parameters of the offshore wind farm, which have been identified as significant for the scale of its environmental impacts, have been adopted after the 2015 Report prepared for the purpose of obtaining the Environmental Decision. The assessment analyzed whether the proposed modifications to the Project's implementation and operation conditions could affect, the assumptions about the environmental conditions forming the basis for the assessment in the 2015 Report, and how the Environmental Decision formulates the environmental conditions for implementation of the Project's design so as to ensure that its implementation will not cause significant environmental damage, regardless of the technology ultimately selected from among those left to choose as a result of the proposed modification of the Project.

The analytical cycle carried out to achieve this assumption is based on the one used in the 2015 Report prepared for the Environmental Decision, but it has been modified and adapted to the needs of carrying out the procedure for amending the Environmental Decision. A diagram showing the interrelationship between emissions/disturbances and their sources, environmental impacts and project parameters is shown in Figure 1 below.

Figure 1. Diagram of the relationship between emissions/disturbances and their sources, environmental impacts and project parameters

	Emission
	Source of emissions
	Features of emission sources
	Impact
	Direct receptor
	Intermediate receptor
	Features of receptors
	Receptor sensitivity
	Impact thresholds
	Emission thresholds
	Parameter thresholds for emission sources

In this cycle, a number of activities and analyses were carried out, the results and conclusions of which are presented in the following volumes and chapters of the EIA Report. Information on the next steps in the executed process of assessing the environmental impact of OWF BIII, is presented below.

- Preparatory stage (completed for the development of the 2015 Report):
    - identify the components of offshore wind farms and the technologies, equipment and processes that may be applicable during the construction, operation and decommissioning of OWFs;
    - to determine, based on the available literature and expert consultations, the possible impacts of offshore wind farms on various environmental elements;
    - identification of elements of the marine environment that are sensitive to particular direct impacts of offshore wind farms;

- identify sources of emissions and environmental disturbances caused by offshore wind farms;
- identification of factors determining the occurrence and scale of impacts:
- venture side,
- on the environmental side,
- identify linkages in the marine ecosystem that may cause secondary impacts;
- planning an environmental research program to provide information on resources and their condition and sensitivity to impacts from the BIII OWF.

- Evaluation stage:
  - verification of the occurrence in the zone of influence of OWF BIII of elements of the marine environment, sensitive to impacts from offshore wind farms, their sensitivity to impacts and interrelationships between them (on the basis of the results of the environmental research program conducted for the Project supplemented by the available results of subsequent studies of the marine environment and the current knowledge of the impacts of offshore wind farms);
  - determination of the parameters adopted during the assessment in the 2015 Report as the basis for conducting the environmental impact assessment, and the parameters approved by the Environmental Decision;
  - determine the impact of changing the conditions of implementation and operation of the BIII OWF on the sources of emissions and disturbances that the BIII OWF may cause, and verify the parameters of the project affecting the occurrence and scale of impacts under the recognized environmental conditions;
  - analysis of the impact of changing the conditions of implementation and operation of the BIII OWF on the scale of impacts caused by the BIII OWF and verification whether the thresholds of significance of impacts on individual environmental elements may be exceeded:
    - at the unit impact of individual project components,
    - with cumulative impacts across the project,
    - when cumulating with other plans and projects,
    - analysis of unplanned impacts,
    - analysis of transboundary impacts,
  - analysis of the impact of changing the conditions of implementation and operation of OWF BIII on the need to change the minimization measures specified in the Environmental Decision and their impact on reducing the scale of impacts;

- assessment of the impact of changing the conditions of implementation and operation of the BIII offshore wind farm on impacts on the integrity, coherence and object of protection of Natura 2000 areas;

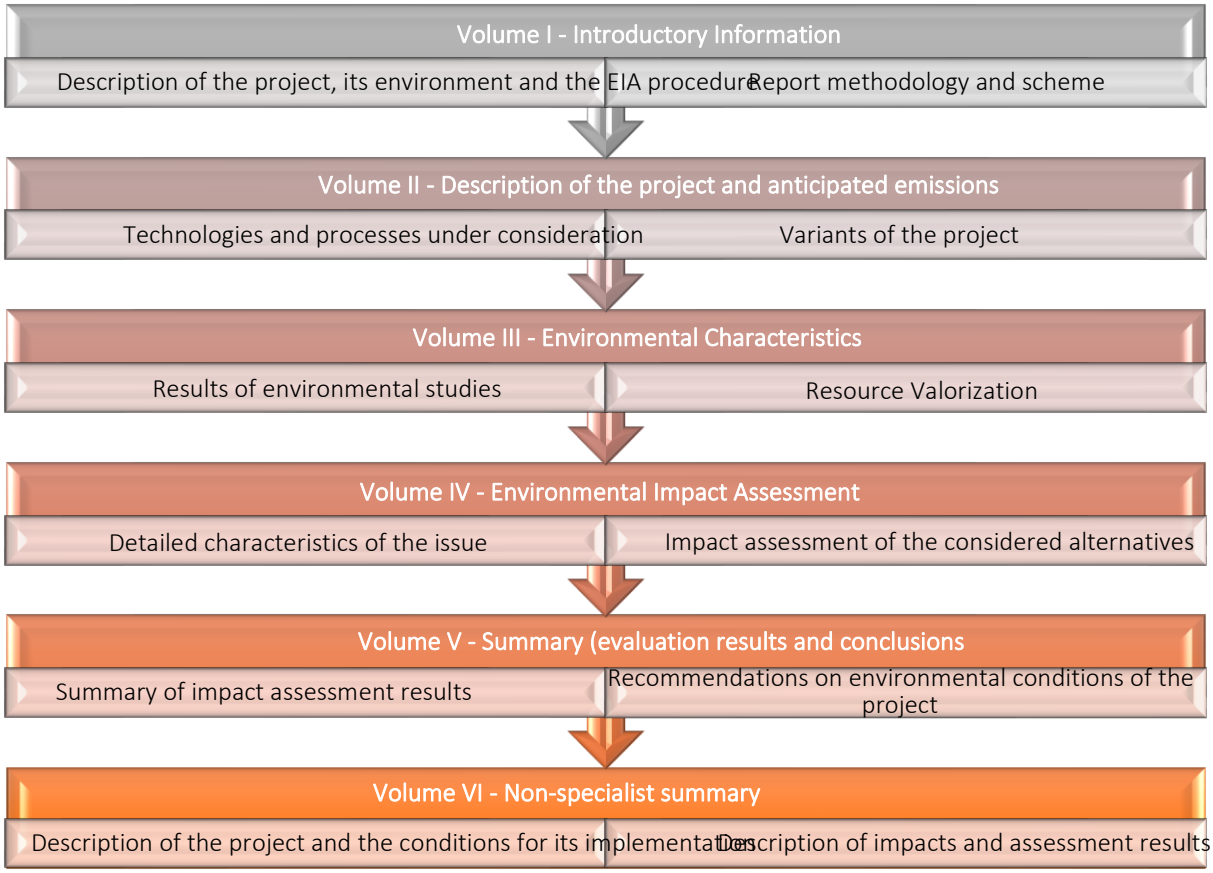
Application stage:

- indication whether the modification of the conditions for implementation and operation of OWF BIII changes the nature of impacts, as well as determination of changes in the scope or intensity of impacts as a result of changes in the conditions for implementation and operation of OWF BIII specified in the Environmental Decision;
- indication whether the assumed modification of the conditions for implementation and operation of the BIII OWF affects other conditions for implementation and operation of the Project, including those relating to minimization measures, monitoring or post-execution analysis.

3. Scheme of the Report EIA

The results and conclusions of all the activities described above are presented in this EIA Report. Due to the very large amount of material and data, and the multithreaded nature of the study, it has been divided into six separate volumes, and each volume has several to a dozen chapters. Each chapter covers a separate topic, described holistically so as to characterize the issue as comprehensively as possible. The following is basic information about the content and purpose of the following volumes of the Report.

Figure 2. Scheme of the EIA Report



I. Volume I - Introductory Information - presents basic information about the project and its political and legal and procedural environment, and refers to the impact of the project's implementation on the environmental objectives set out in strategic documents. It describes the qualification of the project for the environmental impact assessment procedure, describes the requirements for conducting public consultations, and presents the methodology of the environmental impact assessment and the scheme of the Report.

II. Volume II - Description of the project and anticipated emissions/disturbances - is devoted to the description and detailed characteristics of the project to be assessed, and describes all technologies and processes that can be used in the construction, operation and decommissioning of the BIII OWF, indicating the basic technical parameters of individual solutions. In this case, the project description covers the entirety of the BIII OWF after the proposed modifications, as in many cases it is not possible to describe the very essence of the proposed modification without describing the project element that is subject to the modification, as well as the anticipated emissions/disturbances of the modification itself without referring to the emissions caused by the modified element affecting emissions. The description of technologies, processes and their parameters is summarized in a matrix of relationships between the parameters of the various elements of the project and emissions and disturbances, the type of major primary and secondary impacts, and factors affecting the scale of impacts. The following chapters in this volume also characterize in detail such OWF emissions and disturbances as waste and wastewater, noise, hydrographic disturbance and unplanned events. The Report considers as disturbance any environmental interference

caused by the project, which may cause changes in the functioning of the ecosystem (both negative and positive), which are not emissions. The last chapter also describes and characterizes projects that may cause cumulative impacts of OWF BIII. However, it should be emphasized that Volume II does not assess the impact of OWF BIII, and the impacts described here are intended to indicate the possible potential impacts of the offshore wind farm. The description of the project and its parameters and processes associated with its implementation and potential impacts, also takes into account all the elements in this regard, necessary to carry out the stage of reconnaissance (screening) in assessing the impact on the integrity, coherence and object of protection of Natura 2000 areas. The impacts of OWF BIII in modified parameters are described, characterized and assessed in detail in Volume IV. Also in this volume (IV), all the necessary elements of the Natura 2000 impact assessment at the screening stage and the proper assessment, if required, have been performed.

III. Volume III - Characterization of the Environment - presents in the following chapters the conclusions of the performed environmental research program and other available sources of environmental information, including the characterization and valorization of the valuation of individual elements of the marine ecosystem in the zone of potential impacts of the BIII OWF. The resultant reports of the environmental research program have been attached to the Report in the form of appendices, prepared according to the same scheme to enable their joint use at the impact assessment stage. Descriptions of the condition of the environment and individual species fulfill the requirements for characterization of species that are the subject of protection of Natura 2000 areas for the purpose of assessing the impact on the integrity, coherence and object of protection of these areas at the stage of reconnaissance. In characterizing the environment, the available current data on the environment in the area of the project were used, derived from studies carried out for neighboring OWF projects and state environmental monitoring.

IV. Volume IV - Impact Assessment - presents all the legally required elements of the project's environmental impact assessment, with the following chapters performing an assessment of the impacts resulting from the modification of the parameters of the BIII OWF on subsequent elements of the marine environment, including the integrity, coherence and object of protection of Natura 2000 areas. It is in this volume that all potential impacts of the Project on individual elements of the marine ecosystem are described in detail, the key parameters of emissions and disturbances are indicated, the impact of modifications to the parameters of the BIII OWF on the nature, extent and intensity of impacts caused by the variant of implementation of the BIII OWF, for which the Environmental Decision was issued, at all stages of the project, i.e. construction, operation and decommissioning of the BIII OWF, are determined. Cumulative impacts were also characterized here. All characterizations and impact assessments also take into account the requirements for assessing impacts on the integrity, coherence and object of protection of Natura 2000 sites. In addition, in each chapter there is a separate subsection describing the results of the stage of identification of impacts on Natura 2000 areas, and, if it is found necessary to carry out a proper assessment, also its course and results.

All the chapters that make up Volume IV were made according to a standardized template. The unification of EIA chapter templates was intended, among other things, to enable cross-

comparison of assessments of different environmental elements, in order to capture interrelationships and direct and indirect impacts. It also made it much easier to summarize the assessment.

V. Volume V - Summary (assessment results and conclusions) - presents the complete results of the assessment of the impact of the proposed changes to the Project in the parameters approved in the Environmental Decision on the environment as a whole, including on the integrity, coherence and subject of protection of Natura 2000 areas, formulates conclusions and recommendations on the environmental conditions for the implementation of the Project, and also refers to all formal requirements that the EIA Report must contain in the result and conclusion part.

VI. Volume VI - Non-specialist Summary - is a very important element of the Report for maintaining the transparency of the EIA procedure and ensuring public participation. It contains all the most important information about the project, its impacts, environmental conditions, the assessment methodology and its results, as well as recommendations on environmental conditions for the implementation of the project.

4. Methodology evaluation

4.1. Stage preparatory

In the first stage of the environmental impact assessment process for the BIII OWF, analytical activities performed for the environmental impact report prepared for the Environmental Decision were used to determine:

- possible impacts of offshore wind farms on individual environmental elements;
- elements of the marine environment that are sensitive to particular direct impacts of offshore wind farms;
- emission sources and environmental disturbances of offshore wind farms;
- factors determining the occurrence and scale of impacts:
    - venture side;
    - on the environmental side;
- linkages in the marine ecosystem that can cause secondary impacts.

The linkage matrix prepared on the basis of the results of the above work, presented in the table in the next chapter, provided the basic tool for assessing the impact associated with modifying the parameters of the BIII OWF.

4.2. Matrix links

The most important element of the environmental impact assessment of the proposed changes to the Project in the parameters approved in the Environmental Decision was to determine the relationship

between the changed technical parameters of all potential emission sources and the possibility of impacts that could permanently, irreversibly disturb the functioning of the marine environment.

The tool used for this purpose was the created matrix of "emission-source-emission-impact-receptor" relationships, which was created for the environmental impact report prepared for the proceedings under which the Environmental Decision was obtained. It is presented in a table summarizing the characteristics of the technologies and processes considered in the design of the BII offshore wind farm, presented in Volume II, Chapter 7.

Table 1. Template of the matrix of interrelationships of potential emissions and disturbances caused by the OWF and their sources, direct and indirect impacts on the environment and the factors determining them, juxtaposed with the technological parameters of the most far-reaching scenarios for the BIII OWF

Type of emission or disturbance	Source of emissions	Type of impacts	What elements of the ecosystem are directly affected	Linkages (indirect impacts)	Environmental factors affecting the scale of impact	Parameters of the project affecting the scale of impact	NIS 2015	Project - variant selected for implementation (Project after update)

Using the project's interaction matrix behind the environment, the interactions between different impacts and the mechanisms of transfer of impacts within the ecological linkages in the marine ecosystem were also verified. Then it was determined between which elements of the environment and how the various direct and indirect impacts will cumulate.

In addition, for the assessment of individual relevant species/habitats susceptible to impacts from the assessed project, individual linkage matrices were performed to determine the relationship between the characteristics of the assessed species/habitat, local environmental conditions, possible impact linkages and project parameters, in terms of the scale and effects of potential impacts. A template for such a matrix is presented in Table 2.

Table 2. Matrix template for linking individual characteristics, environmental conditions and technical parameters for assessing impacted species and habitats

Species	Determinants of OWF BIII affecting the scale of impacts	Direct impacts	Indirect impacts	Source of emissions	OWF parameters affecting the impact
Characterization of the behavioral and ecological characteristics of the species that affect sensitivity to impacts from the OWF	Abiotic				
	Biotic				

4.3. Stage evaluation

4.3.1. Identification of objects evaluations

As mentioned earlier, the first activity, starting the stage of environmental impact assessment of the modification of the parameters of the BIII OWF, was to determine the subject of the assessment, that is, to verify the presence in the zone of influence of the BIII OWF of elements of the marine environment sensitive to impacts from offshore wind farms.

Identification of the evaluation subjects took place at the stage of the research program conducted for the Project. The selected abiotic, biotic and socioeconomic elements of the environment have been studied, the results of which can be found in Volume III of the Report. These results, supplemented by other available environmental information, became the basis for the assessment.

The identified environmental elements that may be affected by the farm are shown in the table below.

Table 3. Technical scope of the environmental impact assessment

Type of element	Subject of impact
Abiotic elements	Hydrological and hydrochemical conditions
	Seabed
	Bottom sediments
	Mineral resources
Biotic elements	Benthic and benthic habitats
	Ichthyofauna
	Marine mammals
	Seabirds
	Birds flying over the farm area
	Bats
	Protected areas and sites and ecological corridors
	Biodiversity
Natura 2000 areas	Object of protection of areas in the zone of influence
	Integrity of individual areas
	Consistency of the Natura 2000 network
Socio-economic elements	Fishing
	Shipping
	Military operations

Type of element	Subject of impact
	Military aviation
	Civil aviation
	Radar and communications systems
	Landscape
	Tourism and recreation
	Health and life of people
	Cultural heritage
	Climate

The assessment of the impact of the project on the environmental components indicated above, in the variant selected for implementation and the rational alternative variant, as well as in cumulation with other projects, is presented in the following chapters of Volume IV of the Report.

4.3.2. Identification impacts

Identification of all possible impacts of the project on a given environmental component, including on the integrity, coherence and object of protection of Natura 2000 areas, was carried out based on:

- a description of the project - a preliminary technical concept and a timetable for project implementation;
- expert knowledge - experience in the environmental impacts of offshore wind farms, accumulated during the implementation of other projects of this type;
- knowledge of the baseline state of the environment, gathered on the basis of available literature and other publicly available information (including that made available by the relevant authorities) and the results of the pre-execution environmental research program dedicated to the project;
- interactions of the project with the environment - a matrix summarizing the possibility of interaction of the project with the environment, taking into account all the previously identified receptors, which is presented in section 4.2 above. Potential impacts were then analyzed in detail in the context of individual environmental elements, taking into account the criteria that are described in the following section.

The environmental impact assessment assessed the residual significance of impacts, i.e. after the application and implementation of measures to minimize individual negative impacts.

A description of any **potential** impacts of the project on a particular environmental component is always included in Chapter 7 of each Assessment Section of Volume IV. On the other hand, the **evaluation of** the modification of parameters for the implementation and operation of the BIII offshore wind farm was performed in Chapter 9 of each evaluation section in Volume IV. The results of the impact assessment of the BIII OWF update on Natura 2000 sites are presented in Chapter 12 of each section.

4.3.3. Determination of the spatial scope evaluation

Determining the spatial scope of the assessment was done by indicating the area that may be affected by the project.

The extent of individual impacts varied, depending on the environmental conditions (e.g., the type of sediment conditioning the turbidity of the water), the environmental element (e.g., the sensitivity of marine mammals to underwater noise) and the type of impact (e.g., the extent of underwater noise impacts on marine mammals, the extent of impacts associated with the spillage of toxic chemicals into the water, which can spread over long distances).

Also, the ranges of potential impacts on Natura 2000 sites were analyzed individually to individual potential impacts on these sites. This is because the extent of potential impacts on the habitats that are the subject of protection of marine areas is different, and the extent of potential impacts on the integrity of areas protecting bird wintering grounds is different.

4.3.4. Determination of the time scope evaluation

Determining the temporal scope of the assessment consisted of indicating the timeframe in which individual impacts may occur, determined by the successive stages of the project, i.e. the construction stage, the operation stage and the decommissioning stage.

4.3.5. Determine the importance of resources environment

Not all species (habitats, assemblages, objects) found during environmental surveys are susceptible to impacts associated with OWF implementation. Not all species and habitats potentially sensitive to impacts from the OWF are protected or endangered, or important for ecosystem functioning. Thus, another element of the assessment was to assign each impact object (environmental resource) one of five values (insignificant, small, medium, large or very large). The assessment of significance was made on a case-by-case basis for each resource, based primarily on the applicable legislation (species protection status, etc.), knowledge of the resource's baseline condition (including the results of the pre-implementation environmental research program dedicated to the project), and knowledge of its sensitivity (sensitivity as a function of the resource's ability to adapt to potential change resulting from the project and its ability to return to its baseline condition). When assessing the importance of individual resources, their conservation status was also taken into account, especially within the European Natura 2000 system. Species and habitats, which are the subject of protection of Natura 2000 areas or have a significant impact on maintaining the integrity of these areas, or listed in the annexes to the Habitats or Birds Directive, were categorized as being of high or very high importance.

The classification of the importance of receptors (environmental resources) and the general definitions of each category are described in the table below. For individual resources/receptors, their importance was categorized individually each time, based on specific criteria.

Table 4. Classification of the importance of objects of influence (environmental resources)

Category of importance of the resource	Definition of	
Insignificant	Abiotic elements/Biotic elements/Socioeconomic elements:	A resource of insignificant importance to the functioning of the ecosystem, abundant (common), not susceptible to changes associated with the implementation of the project or having the ability to adapt to changes in the environment.
Small	Abiotic elements:	Resources of low importance to ecosystem functioning or resources of moderate importance that are not very susceptible to changes associated with the implementation of the project or have the ability to adapt to changes in the environment or natural and quickly return to baseline.
	Biotic elements:	Species/habitats that are not protected or endangered, abundant (common), of little importance to ecosystem functioning, not very susceptible or with the ability to adapt to changes in the environment, or to recover naturally and quickly.
	Socio-economic elements:	Socio-economic resources of little importance in terms of economic, cultural and social value, with little susceptibility or ability to adapt to changes in the environment, or natural and quickly return to baseline.
Medium	Abiotic elements:	Resources of moderate or high importance for ecosystem functioning, having minor
		or lacking the ability to adapt to changes in the environment.
	Biotic elements:	Species/habitats that are not protected, globally abundant but rare in the Baltic Sea region, or species that are protected but not susceptible or not very susceptible to impacts from the project. Species of importance to ecosystem functioning or species with declining but not threatened populations.
	Socio-economic elements:	Socio-economic resources of little importance in general, but of importance to the resource base or livelihoods locally.
Large	Abiotic elements:	A resource that is important but not essential to the functioning of the ecosystem, with neither the ability

Category of importance of the resource	Definition of	
		to adapt to changes in the environment nor the ability to fully return to baseline.
	Biotic elements:	Species/habitats that are protected under national and/or international law, are rare and endangered nationally, and are important for ecosystem functioning.
	Socio-economic elements:	Socio-economic resources protected under national and/or regional laws or strategies that are important to the resource base or livelihoods on a regional scale.
Very large	Abiotic elements:	A resource that is fundamental and essential to the functioning of the ecosystem, without the ability to adapt to changes in the environment or the ability to return to a baseline.
	Biotic elements:	Species/habitats that receive special protection under national and/or international law, are internationally rare and endangered, and are essential for ecosystem functioning.
	Socio-economic elements:	Socio-economic resources protected under national or international laws or strategies, which are important to the resource base or livelihoods on a national scale, for which project impacts may significantly prevent their use.

The result was the identification of environmental resources that may be of such significance that impacts on them should be assessed, and resources that will not be assessed.

4.3.6. Determination of the nature and type of impact

At this stage, each potential impact was classified in terms of:

- its nature:
  - positive impact - resulting in an improvement over the baseline;
  - negative impact - causing an adverse change from the baseline;
  - no impact;
- his type:
  - direct impact - resulting from direct interaction between the activity planned under the project implementation and the environmental resource;

- indirect impact - resulting from other activities that are not directly related to project implementation;
- secondary - not resulting from a direct interaction between the activity planned in the implementation of the project and the environmental resource, postponed in time in relation to such activity, which may extend beyond the area of implementation of the activity; classified as a consequence of direct or indirect impact;
- cumulative - occurring in conjunction with other impacts associated with the development of other projects that affect the same environmental resources.

4.3.7. Determination of the magnitude of impact

Another element of the assessment was to determine the magnitude of the impact. The magnitude of the impact is a function of several variables, which include:

- scale of the impact, in relation to the resources/populations affected:
  - local - impact on populations/socio-economic elements of local importance;
  - regional - impact on regionally significant populations/socio-economic elements;
  - national - impact on populations/socio-economic elements of national importance;
  - international - impact on internationally significant populations/socio-economic elements.

  The range (local, regional, national, international) was determined individually for each environmental element, taking into account the specifics of population distribution. Any additional criteria (e.g., distance) for the detailed definition of individual categories of the scale of impact, including impacts on the integrity, coherence and object of protection of Natura 2000 sites, are indicated in the individual impact assessment chapters in Volume IV.
- frequency of impact:
  - o one-time - an impact that is discontinuous in time, which is certain to occur once and will not recur in the analyzed time horizon;
  - recurrent - an impact that is discontinuous in nature over time, which may occur repeatedly in the analyzed time frame;
  - permanent - an impact of a continuous nature, continuing uninterruptedly over the analyzed time horizon;
- duration of impact:
  - temporary - an impact that ceases when the activity that is the source of the impact ends, and the receptor of the impact returns to its initial state with the cessation of the activity that was the source of the impact; also intermittent, sporadic impacts;

- short-term - a time-limited impact that does not cease with the termination of the activity that gave rise to it and persists for no more than 1 year/vegetation cycle after the end of that activity;
- medium-term - a time-limited impact that persists from 1 year/vegetation cycle to 3 years/vegetation cycle after the cessation of the activity that gave rise to it; also an intermittent, sporadic impact regularly recurring over an extended period of time (e.g., seasonal disturbances);
- long-term - an impact that persists for more than 3 years/vegetation cycles from the cessation of the activity that gave rise to it, or an impact that causes permanent changes in the affected resources that persist after the end of operation.

- intensity of impact:
  - low - impact at the threshold of detection;
  - medium - an impact that noticeably affects the functioning of a resource/species/population/ecosystem/Natura 2000 area (e.g., active avoidance response noticeable in individuals of particular species, change in status of a social group), but does not affect its structure/parameters of functioning;
  - large - impact significantly affecting the functioning of a resource/species/population/ecosystem/Natura 2000 area (e.g., temporary loss of hearing - TTS, long-term change in the status of a social group), affecting its structure/parameters of functioning;
  - very high - impact causing a complete change in the functioning of a resource/species/population/ecosystem/Natura 2000 area, a visible change in the structure/parameters of functioning (e.g., damage to vital functions, permanent/intergenerational changes in the status of a social group);
- reversibility:
  - reversible impact - it ceases to be felt immediately or within a short time after the cessation of the activity that gives rise to it;
  - irreversible impact - felt even after the cessation of the activity that gave rise to it, the resource does not return to the baseline despite the implementation of minimization measures.

The magnitude of the impact was then classified into one of five categories: no change, insignificant, small, moderate, large, according to the matrix shown in the table below. The matrix does not include frequency and reversibility of impact. These categories were additionally described as part of the evaluation.

Table 5. Impact magnitude assessment matrix

Magnitude of impact	Scale of exposure	Duration	Intensity
No change	Without losing the resource, no influence on the structure and operation of the resource		
Insignificant	Local	Momentary	Low
	Local	Momentary	Average
	Local	Momentary	Large
	Local	Momentary	Very large
	Local	Short-term	Low
	Local	Short-term	Average
	Local	Short-term	Large
	Local	Medium-term	Low
	Local	Medium-term	Average
	Local	Long-term	Low
	Regional	Momentary	Low
	Regional	Momentary	Average
	Regional	Momentary	Large
	Regional	Short-term	Low
	Regional	Short-term	Average
	National	Momentary	Low
Small	Local	Short-term	Very large
	Local	Medium-term	Large
	Local	Long-term	Average
	Regional	Momentary	Very large
	Regional	Short-term	Large
	Regional	Medium-term	Low
	Regional	Medium-term	Average
	Regional	Long-term	Low
	National	Momentary	Average
	National	Momentary	Large
	National	Short-term	Low

Magnitude of impact	Scale of exposure	Duration	Intensity
	National	Short-term	Average
	National	Medium-term	Low
	International	Momentary	Low
	International	Momentary	Average
	International	Short-term	Low
Moderate	Local	Medium-term	Very large
	Local	Long-term	Large
	Local	Long-term	Very large
	Regional	Short-term	Very large
	Regional	Medium-term	Large
	Regional	Medium-term	Very large
	Regional	Long-term	Average
	Regional	Long-term	Large
	National	Momentary	Very large
	National	Short-term	Large
	National	Short-term	Very large
	National	Medium-term	Average
	National	Long-term	Low
	International	Momentary	Large
	International	Short-term	Average
	International	Medium-term	Low
Large	Regional	Long-term	Very large

	National	Medium-term	Very large
	National	Long-term	Average
	National	Long-term	Large
	National	Long-term	Very large
	International	Momentary	Very large
	International	Short-term	Large

Magnitude of impact	Scale of exposure	Duration	Intensity
	International	Short-term	Very large
	International	Medium-term	Average
	International	Medium-term	Large
	International	Medium-term	Very large
	International	Long-term	Low
	International	Long-term	Average
	International	Long-term	Large
	International	Long-term	Very large

4.3.8. Determining the importance of impact

The significance of each impact was assessed taking into account the importance of the resource/impact object and the magnitude of the impact, using the impact assessment matrix shown in the table below.

Depending on the relationship between the importance of the resource/receptor and the magnitude of the impact, each impact was classified into one of six categories as an impact: very large, large, moderate, small, negligible, no change.

The environmental impact assessment assessed the residual significance of impacts, i.e. after the application and implementation of measures to minimize individual negative impacts.

Table 6. Impact significance assessment matrix

Importance of the resource/receptor	Magnitude of impact				
	Large	Moderate	Small	Insignificant	No change
Very large	Very large	Large	Moderate	Small	No change
Large	Large	Moderate	Small	Small	No change
Medium	Moderate	Small	Small	Skip	No change
Small	Small	Small	Skip	Skip	No change
Insignificant	Small	Skip	Skip	No change	No change

The different categories of impact significance can be generally defined according to the terminology shown in the table below.

Table 7. General definitions of each category of impact significance

The significance of the impact	General definition
Very large	A change in a resource/receptor of international, national significance that occurs despite the application of minimization measures and may lead to a loss or significant changes in structure or
	parameters of the resource/receptor/ecosystem, leading to serious disruption of its functioning, including loss of proper conservation status, including Natura 2000 sites. Usually impacts of a negative nature, which are key in the process of determining the environmental conditions of the project.
Large	Large or very large changes in the resource/receptor/ecosystem (both negative and positive in nature) that occur despite the application of minimization measures. Changes are considered to be regionally significant, may affect the achievement of national, regional or local goals, including proper conservation status, including Natura 2000 areas, or to violate legislation.
Moderate	Average changes in the resource/receptor/ecosystem that occur despite the application of minimization measures. The changes are considered significant locally, but not nationally or internationally, are within the norms, and are not important for the preservation of proper conservation status.
Small	Minor changes in the resource/receptor that occur despite the application of minimization measures. The changes are within the norm, and are often indistinguishable from the natural level of change. They may be considered locally, but they are not central to the process of determining the environmental conditions of the project.
Skip	Imperceptible changes in the resource/receptor that occur after application of minimization measures.

Significant impacts include those impacts from the large and very large categories (according to the classification shown in Table 6 and Table 7) that cause long-term, irreversible deterioration of the environment or an element of it that threatens its proper functioning. With regard to the assessment of impacts on Natura 2000 sites, both categories fall into those likely to cause significant impacts on the preservation of the proper conservation status of Natura 2000 sites, as well as their integrity and coherence. Both categories found at the screening stage predetermine a proper assessment. The "very large" category found as a result of the proper assessment qualifies the project as having a significant impact on Natura 2000 sites.

In the case of this Report, taking into account its specific nature related to the proceedings on the amendment of the decision on environmental conditions, the key stage of the conducted impact assessment was to determine how the modification of the parameters of the implementation and

operation of the BIII OWF affects the identified impacts of the BIII OWF as it was subjected to the environmental impact assessment during the proceedings on the decision on environmental conditions, which ended in obtaining the Environmental Decision.

The assessment of the impact of modifications to the Project's implementation and operation parameters could be categorized under five thresholds. The following table shows the classification used

Table 8. General definitions of the different categories of impact of updating the parameters of the Project

The impact of updating the parameters of the Project on the significance of the impact	General definition
Significant increase in impacts	Changing the parameters of implementation and operation of the Project affects impacts to such an extent that it leads to a change in impact significance relative to the assessment conducted in the 2015 Report by increasing impact significance by one degree or more
Increasing impacts	Changing the parameters of implementation and operation of the Project affects impacts to the extent that it leads to an increase in impacts, but this change will not change the degree of assessment of significance
No impact	Changing the Project's implementation and operation parameters does not affect the impacts assessed in the 2015 Report
Reducing impacts	Changing the parameters of implementation and operation of the Project affects impacts to the extent that it leads to a reduction in impacts, but this change will not change the degree of assessment of significance
Significant reduction in impacts	Changing the parameters of implementation and operation of the Project affects impacts to such an extent that it leads to a change in impact significance compared to the assessment carried out in the 2015 Report, reducing impact significance by one degree or more

It should be noted, however, that the above classification is a theoretical assumption, due to the nature of the modifications to the parameters of implementation and operation of the Project, i.e. the fact that the changes introduced are of a limiting nature, whether the size of the parameters of the Project, allowed by the Environmental Decision, or the range of possible technologies to be applied, and in the case of changes in the unit parameters of wind power plants being increased, they were combined with a change in the number of plants to be implemented, leading to multiple compensation of the unit

impacts so caused. As a result, the first two degrees of impact assessment of the Project's parameter update could not occur, and the scale of impact in practice was limited to three values - no impact, reduced impacts, significant reduction of impacts.

For impacts that were not assessed in the 2015 Report due to lack of knowledge or a change in legal requirements in this regard, the unmodified methodology of the 2015 Report was used.

4.3.9. Assessment of impacts cumulative

Within the framework of the environmental impact assessments of the project for all resources/subjects of the assessment, analyses of cumulative impacts were also carried out, taking into account the different types of activities undertaken as part of the implementation of the project in question, as well as activities carried out or planned for other projects carried out by external entities. The analyses included activities carried out or planned for projects of a similar or different nature (offshore wind farms, power cables, etc.) that meet the following criteria:

- project built, in operation or under construction;
- a project for which a decision on environmental conditions has been issued, for which construction activities have not yet begun at the stage of preparing this EIA report;

The list of projects that were considered in the assessment of cumulative impacts is included in Chapter 13 of Volume II of the Report.

For each resource/receptor, impacts that may cumulate during the various stages of the project were individually identified, and then the significance of these impacts was assessed by classifying them into one of 6 impact categories: no impact, negligible impact, small impact, moderate impact, high impact or very high impact, according to the scale presented in the table below. The assessment of cumulative impacts also includes issues of cumulative impacts on the integrity, coherence and object of protection of Natura 2000 sites.

The assessment of the significance of cumulative impacts was, as far as possible, performed in accordance with the general assessment methodology adopted and described earlier, but its scope and depth were strongly dependent on the information and quality of documentation available for each project. Where the scope of information and the quality of available documentation were insufficient to perform the assessment in accordance with the adopted methodology, the assessment was descriptive in nature, and the classification of impacts was based on available knowledge and past experience of other similar projects.

Table 9. Classification of cumulative impacts

No cumulative impacts
Cumulative impacts negligible
Cumulative impacts small
Cumulative impacts moderate
Cumulative impacts high

Cumulative impacts very high

The definitions of the categories of cumulative impacts are the same as those shown in the table above.

The assessment of cumulative impacts is always a part of the assessment for the different stages of the project (Chapter 9) of each assessment chapter of Volume IV.

4.3.10. Assessment of impacts unplanned

Unplanned impacts result from sudden unplanned events or failures that are not related to activities included in the project schedule (e.g., leakage of toxic substances into the water due to a collision between two vessels).

In assessing the significance of unplanned impacts, additional factors were taken into account, i.e. the probability of an event that will be the source of the impact and its potential consequences (e.g., taking into account the criteria indicated in sections 4.3.6 - 4.3.7 of this document).

The assessment of the significance of unplanned impacts was carried out on the basis of expert knowledge and past experience with similar projects.

The assessment of unplanned impacts also takes into account the potential impact on the integrity, coherence and object of protection of Natura 2000 sites.

A description of unplanned events that could potentially occur at OWF BIII is provided in Volume II, Chapter 12.

The assessment of unplanned impacts is always found in Chapter 11 of each assessment chapter of Volume IV.

4.3.11. Assessment of impacts transboundary

According to the provisions of the Espoo Convention[1], transboundary environmental impact means any impact, not exclusively of a global nature, in an area under the jurisdiction of a Party, caused by a planned activity, the physical cause of which is wholly or partly located in an area under the jurisdiction of another Party.

In accordance with the adopted methodology, the assessment of transboundary impacts is conducted as part of the environmental impact assessment described in Section 4.3. of this document. Identification of transboundary impacts is done at the stage of categorizing their magnitude. Among others, those impacts whose scale of exposure is described as international - the impact goes beyond the boundaries of the Polish exclusive economic zone (see section 4.3.7. of this document) are assessed.

The assessment of transboundary impacts also takes into account the results of the assessment of impacts on Natura 2000 sites, especially on their coherence. **The assessment of transboundary impacts is always found in Chapter 13 of each assessment chapter of Volume IV.**

[1] Convention on Environmental Impact Assessment in a Transboundary Context, done at Espoo on February 25, 1991. (Journal of Laws No. 96, item 1110)

4.3.12. Assessment of impacts related

Related impacts are understood as a chain of all impacts that may occur in the ecosystem, following the occurrence of an impact on one of its elements. The purpose of assessing associated impacts is to verify that direct impacts on one receptor will not become a source of indirect impacts on another receptor or on the ecosystem as a functional whole, especially in conjunction with direct impacts on that receptor. This is because in such a situation it becomes necessary to apply additional measures aimed at minimizing such impact.

The evaluation of each individual environmental element took into account its interrelationships with other elements of the environment, both in terms of the impact of direct impacts on other elements that indirectly affect the element, as well as the indirect impact of direct impacts of the evaluated element on other environmental components.

The assessment of associated impacts also takes into account the potential for these impacts to affect the integrity, coherence and object of protection of Natura 2000 areas.

The linkages between the various impacts are shown in the linkage matrix in Chapter 7 of Volume II.

4.3.13. Assessment of the impact on the integrity, coherence and object of protection of Natura sites 2000

The subject of the assessment, in accordance with the wording of Article 6 of the Habitats Directive, is only the scope and scale of the impact of the planned project on those elements of the environment for the protection of which individual Natura 2000 areas have been established, as well as the integrity and cohesion of these areas, ensuring their proper state of protection.

As defined in this study:

- The integrity of a Natura 2000 site (Engel J., 2009) is the maintenance of the proper conservation status of those natural habitats and plant and animal populations for the protection of which the site was designated. The integrity of the area also consists of the preservation of ecological structures and processes that are essential for the sustainability and proper functioning of natural habitats and plant and animal populations.
- Coherence (Institute for Sustainable Development) of the Natura 2000 network is the completeness of natural resources in the network and the preservation of functional links between individual Natura 2000 sites at the level of the biogeographical region in the country, ensuring the maintenance in a proper state of protection of natural habitats and species. Consistency refers to the links between Natura 2000 sites, and thus to the ecological corridors that condition the spatial continuity of the entire network. The coherence assessment takes into account:
    - representativeness and numerical criteria;
    - incidence relative to range;
    - fragmentation of space;

- assessment of adequate conservation status based on national natural monitoring.

- On the other hand, the purpose of the analysis is to show whether the project's impacts may reach the scale of **significant impacts, i.e. permanently deteriorating the proper state of protection of habitats and species of birds and bats, for whose protection Natura 2000 areas were established**.

- **The assessment of the impact on the coherence of the Natura 2000 network should take into account the importance of the site for maintaining the coherence of the network in relation to the species and habitats that are protected there.**

The adopted methodology for assessing the impact on the integrity, coherence and object of protection of Natura 2000 sites is based on and follows the guidelines described in:

- a study by the Directorate General - Environment of the European Commission entitled: "Assessment of Plans and Projects Significantly Affecting Natura 2000 Areas - Methodological Guidance on the Provisions of Article 6 (3) and (4) of Habitats Directive 92/43/EEC," November 2001;

- the study "Natura 2000 in environmental impact assessments of projects" by J. Engel (Ministry of Environment, 2009);

- european Commission guidelines "Wind Energy Development and Natura 2000" of October 2010;

- "Guidelines for forecasting environmental impacts of wind farms" by M. Stryjecki and K. Mielniczuk (General Directorate of Environmental Protection, 2011).

To ensure compliance and consistency with the requirements of Directive 85/337 EEC as amended by Directive 97/11 EC (the EIA Directive), and in view of the fact that many projects that are likely to affect a Natura 2000 site will also be projects covered by the EIA Directive, the procedures outlined in these guidelines are similar to those commonly used under the EIA. The guidelines are also consistent with the general approach recommended in European Commission documents on EIA reconnaissance, scoping and verification. In addition, the scope of the EIA Directive includes all plans that require assessment under Article 6 of the Habitats Directive. According to EC guidelines, where projects or plans fall within the scope of activities covered by the provisions of the EIA Directive or the SIA, Article 6 assessments may be part of these assessments. However, within the relevant environmental impact report, the assessments provided for in Article 6 should be clearly distinguished and indicated, or reported separately.

In this report, the assessment of the impact on the integrity, coherence and object of protection of Natura 2000 sites is an immanent part of the performed environmental impact assessment of the proposed changes to the Project in the parameters approved in the Environmental Decision. All the elements of the description of the project, its impacts, the environmental conditions of its implementation take into account the elements necessary to carry out an assessment of the impact on Natura 2000 areas, as demonstrated in the above sections of the description of the methodology for carrying out the EIA.

At the same time, the elements of the Natura 2000 impact assessment are clearly distinguished in the structure of the RIA, through:

a. a separate description of the methodology for assessing the impact on the integrity, coherence and object of protection of Natura 2000 sites;

b. collection of the elements of natura assessment and its results in relation to individual elements of the marine ecosystem (screening and proper assessment, if necessary) in separate chapters No. 12 of each thematic study of Volume IV;

c. a summary of the results of the assessment of impacts on Natura 2000 sites, including indications of required measures to minimize these impacts in a separate chapter of Volume V.

The adopted procedure scheme includes 4 stages of evaluation (the evaluation may end after each of these stages):

- first stage (reconnaissance, preliminary assessment, screening) - the process during which the probable impacts of the project on Natura 2000 areas (individually or in conjunction with other projects or plans) are identified and an analysis is made of whether the anticipated impacts may have a significant impact on these areas;

- the second stage (proper assessment) - assessment of the impact of the project on the integrity of Natura 2000 areas (individually or in conjunction with other projects or plans) in relation to the structure of the areas, their functions and conservation objectives; conducted only if the projected impacts of the project may have a significant impact on Natura 2000 areas; if there are negative impacts, potential mitigation measures are additionally assessed;

- the third stage (impact assessment of the Project update) - the process during which it is analyzed whether the modification of the parameters of implementation and operation of the Project affects the results of the assessment carried out in the 2015 Report, with the classification used to assess the impact of the change as in the assessment of impacts.

The following criteria and factors are considered during the evaluation:

- individual elements of the project that may, individually or in conjunction with other plans or projects, affect Natura 2000 areas;

- any possible direct, indirect or secondary impact of the project (singly or in conjunction with other plans or projects) on Natura 2000 areas, foreseeable as a simple consequence of the following characteristics:

    - size and scale;

    - land occupation;

    - distance from the Natura 2000 area or its fragments of key importance for protection;

    - physical changes resulting from the implementation of the project;

    - emissions (discharged to water or air) and waste;

- transportation requirements;
- duration of construction, operation, decommissioning, etc..;
- cumulative impacts with other projects and plans;
- others,

- all likely changes in the characteristics of the area resulting from:
  - habitat reduction/loss/fragmentation;
  - reduction in population size/decline (changes in density/biomass);
  - changes in the functioning and structure of species and habitats;
  - changes in key indicators of conservation value (water quality, etc.);
- all presumed impacts on the integrity and cohesion of Natura 2000 areas, by virtue of:
  - interference with key relationships shaping the structure of the area;
  - interference with key relationships shaping the area's function;
- significance indicators of the identified impacts, expressed in terms of:
  - losses;
  - fragmentation;
  - interruptions;
  - interference;
  - changes in key elements of the area (e.g., water quality, etc.).

The assessment for the project in question was based on:

- the best available scientific knowledge and expertise;
- existing inventory materials of the area (results of pre-implementation environmental studies);
- existing experience from the implementation of other such projects;
- information on the objects of protection of individual Natura 2000 areas remaining in the zone of potential impacts of the project;
- factors that determine the cohesion and integrity of these areas.

4.3.13.1. Preliminary assessment stage - screening

At the stage of preliminary assessment of the impact on Natura 2000 areas, the assessment of the impact of OWF BIII on the environmental element was carried out analysis to answer the following questions:

- What is the zone of potential impacts of the modified BIII OWF on the environmental element?
- Are there Natura 2000 sites in the zone of potential impacts?
- Are species or habitats sensitive to the impacts of the modified BIII OWF the subject of the site's protection?
- Is the modified BIII OWF a project related to or necessary for the management of the area?
- Whether the modified BIII offshore wind farm may cause significant impacts on:
    - the object of protection of Natura 2000 sites located in the zone of its potential impacts?
    - the integrity of the areas within the zone of its impacts?
    - the coherence of Natura 2000 sites?
- What is the zone of potential impacts of the modified BIII offshore wind farm in conjunction with other projects on the environmental element?
- Are there Natura 2000 sites in the zone of potential impacts?
- Are species or habitats sensitive to the impacts of the modified BIII OWF in conjunction with the impacts of other projects the subject of the site's protection?
- Whether the modified BIII offshore wind farm, in conjunction with other projects, may cause significant impacts on:
    - the object of protection of Natura 2000 sites located in the zone of its potential impacts?
    - the integrity of the areas within the zone of its impacts?
    - the coherence of Natura 2000 sites?

4.3.13.2. Evaluation stage proper

In the case of an affirmative answer to question 5 or 9 above, while answering question 4 in the negative, it was necessary to perform a proper evaluation, which included analyses to answer the following questions:

- Which area's conservation objectives are likely to be significantly disrupted by the modified BIII OWF, either alone or in cumulation with other projects?
- What impacts of the modified BIII OWF, either alone or in cumulation with other projects, may cause significant impacts on the integrity, coherence or object of protection of Natura 2000 areas?
- Are there measures to minimize a given impact that can be effectively applied?
- Will the modified BIII offshore wind farm, alone or in cumulation with other projects, have a significant impact on the integrity, coherence or object of protection of Natura 2000 areas after the application of minimization measures?

4.3.13.3. Impact assessment of the update Projects

Due to the nature of the modification of the parameters of the Project, the impact assessment of the modification of the parameters of the Project could not result in changes that would mean a change in the significance of the impact in such a way that it could lead to an impact on the integrity, coherence and object of protection of Natura 2000 sites.

4.3.13.4. Method of presentation of the results of the Natura impact assessment 2000

The description of the assessment of the impact on the integrity, coherence and object of protection of Natura 2000 areas in the first stage (screening) is presented in the Report in sections on individual environmental elements in Chapter 12 of each assessment report included in Volume IV.

In the event that it is necessary to carry out an assessment specific to the possibility of significant impacts on the integrity, coherence or object of protection of Natura 2000 areas as a result of the impact of the modified BIII OWF on a particular environmental element, the course and results of this assessment, carried out taking into account the associated impacts on other environmental elements, were presented in Chapter 12 of the respective assessment report included in Volume IV. A summary of the assessment of impacts on Natura 2000 sites, summarizing all the results from the screening and proper assessment stage, as well as recommendations on the need for minimization measures, is presented in Volume V.

4.4. Stage applications

Conclusions as to the impacts caused by the BIII offshore wind farm after modifications in the implementation and operation of the Project first include prejudgments as to the impact of modifications on the nature, extent and intensity of impacts.

These conclusions were then the starting point for analyses of the conditions for implementation and operation of the remaining conditions specified in the Environmental Decision, as well as possible proposals for their modification.

For impacts that were not assessed in the 2015 Report due to lack of knowledge or a change in legal requirements in this regard, the unmodified methodology of the 2015 Report was used.

RDEP	Regional Director of Environmental Protection in Gdansk

1. Introduction

The section presents the characteristics of the project, which consists of the construction of an offshore wind farm designated as the Baltic III OWF in modified parameters, proposed within the framework of the present proceedings to amend the decision on environmental conditions. At the same time, this characterization indicates those of the parameters whose modification is proposed and the scope of the proposed modification.

The following sections describe in detail the planned changes to the Project's implementation and operation conditions, as defined by the Environmental Decision. The variant approved by the Environmental Decision included the construction of 120 power plants, while the variant that is the subject of this Report provides for the construction of up to 60 power plants, with some power plant parameters increased beyond the provisions of the Environmental Decision issued. Accordingly, the changes in the project description are primarily related to modifying the parameters of the power plant so that they are in line with the state of the art and the latest solutions offered by technology suppliers. In addition, the changes are due to the progress of design work including the development of a preliminary plan for the farm and the narrowing of the scope of foundation technology. The changes presented will be the subject of both a description of the project and a reference point for conducting an impact assessment.

2. Location

The proposed OWF BIII will be located in the southern part of the Baltic Sea, in the Polish exclusive economic zone according to the location specified in the Environmental Decision[1]. The location of the project is shown in the figure below.

[1] Decision of the Regional Director of Environmental Protection in Gdansk RDOŚ-Gd-WOO.4211.12.2015.KP.22 dated July 7, 2016.

Source: PSZW for OWF BIII

3. Basic elements farms

The Baltic III offshore wind farm will consist of up to 60 wind turbines and one internal offshore substation, as well as submarine power and telecommunications cables.

4. The area of the occupied basin

According to the PSZW, the area designated for the BIII offshore wind farm is about 119.52 square $^{\text{kilometers}}$. This permit includes a condition that elements of the OWF must not be located within a buffer of 500 meters from the inner boundary of the area designated for the farm. Within the boundaries of the area so delineated, all structural elements of the farm must be contained, so it determines the maximum external extent of the rotor, which further limits the area in which foundations can be set. The size of this constraint depends on the radius of the rotor.

The area designated for OWF BIII according to the findings of the Environmental Decision is about 117 $^{\text{km2}}$. According to the conditions set forth in the permit for the erection and use of artificial islands, structures and devices in Polish maritime areas issued for the Project, elements of the OWF may not be located within a buffer of 500 m from the inner boundary of the area intended for the farm. Within the boundaries of the area so delineated, all structural elements of the farm must be contained, so it determines the maximum external extent of the rotor, which further limits the area in which foundations can be set. The size of this constraint depends on the radius of the rotor.

In addition, as a result of the analysis of potential impacts of the project on the environment, at the stage preceding the work on this EIA Report, the Investor made additional restrictions on the use of the OWF development area due to the possibility of a negative impact of the investment on seabirds, in the course of design works, a decision was made to leave the area located in the western-northern corner of the farm undeveloped with power plants, in such a way as to create an unobstructed 5 km wide

corridor undeveloped with power plants, crossing the areas of the Baltic III OWF and Baltica 2 and Baltica3 OWF farms in the SW-NE direction.

Taking the above into account, the Report assumes that the total area of the farm is about 117 ^{km2}, including:

- the area to be developed, according to the conditions set forth in the permit for the erection and use of artificial islands, structures and devices in Polish maritime areas issued for the Project, is about 94 ^{km2};
- the area to be developed, taking into account the exclusion of part of the area of OWF BIII, for the purpose of creating an expensive migration corridor for birds between the groupings of wind power plants belonging to projects located on the northern and northeastern slopes of the Slupsk Shoal, is about 88 ^{km2}.

The aforementioned areas for development were designated in accordance with the regulations of the Law of July 7, 1994. - Construction Law (i.e. Journal of Laws 2021, item 2351, as amended).

The table below gives the geographic coordinates of the boundaries of the farm development area.

Table 2 Geographical coordinates of the boundaries of the BIII OWF development area.

5. Changes in relation to the variant approved by the Decision Environmental Decision

In connection with the implementation of the design work and in view of the proceedings on environmental decisions and decisions in the form of issued environmental decisions for other offshore wind farms located in the vicinity, the ordering party specified in detail the area intended for the implementation of the BIII OWF. The northwestern corner of the area designated for the Project has been excluded from the development of elements of the Project, which will expand the development-free area located between the planned farm and the neighboring offshore wind farm OWF Baltica 2 and OWF Baltica 3.

As indicated by the results of the impact assessments of the OWF projects carried out so far, such a corridor should be about 5 km wide along its entire length and should be located in such a way as to ensure free passage in the NE-SW direction between the power plants located on the northern and northeastern slopes of the Slupsk Shoal. In this regard, it should be emphasized that all the impact assessments of OWF projects carried out so far have been carried out using methodologies based on an envelope description of the parameters of the project and analysis of the most far-reaching scenarios, and the substantive conclusions in the discussed scope are the same.

Since the corridor is intended to reduce the cumulative impact of the projects of different investors, its boundaries should be agreed upon by those investors through whose projects such a corridor would pass, based on scientific considerations. This is due both to the methodological basis of the Natura 2000

impact assessment, but also to the authority's approach to date, as expressed in the legally binding decisions on environmental conditions for the projects of the OWF Bałtyk Środkowy III (hereinafter: OWF BSIII) mark: RDOŚ-Gd-WOO.4211.12.2015.KP.22 dated July 7, 2016 and Polenergia Bałtyk II OWF (originally: Bałtyk Środkowy II OWF, now: IMF Baltic II; hereafter: IMF BII), sign: RDOŚ-Gd-WOO.4211.26.2015.KSZ.20 dated March 27, 2017 and the decision sign: RDOŚ-Gd-WOO.430.3.2021.KSZ.14zpo dated October 26, 2021. The designation of the corridor is to be based, according to the content of the cited decisions, on the guideline that the axis of the designated corridor should coincide with the line that demarcates these water bodies, or, if for scientific reasons the course of the corridor should be different, that the axis of this corridor should be determined in such a way that it causessimilar and comparable economic effects for farms in these water bodies, at the lowest possible cost to the environment. Due to the fact that the location of the corridor providing free passage in the NE-SW direction between the power plants located on the northern and northeastern slopes of Slupsk Shoal was determined in the content of the decision on environmental conditions issued for the project titled "The power plants of Slupsk Shoal". "Offshore Wind Farm Baltica", decision on environmental conditions mark: RDOŚ-Gd-WOO.4211.21.2017.MJ.PW.AJ.37 on January 24, 2020, the designed and presented in this report exclusion area is a consequence and continuation of the conditions indicated in the cited decision, while guaranteeing the preservation of free passage of birds in the NE-SW direction towards the Slupsk Shoal slope. The space excluded from wind turbine development in the northwestern corner of the farm has been designated in consultation with the developer of OWF Baltica3 and OWF Baltica2.

The boundaries of the exclusion area are shown in Table 3 and Figure 4 below.

Table 3 Coordinates of the migration corridor for birds - the area excluded from wind turbine development.

Source: Material Provided by IMF Baltic III.

In connection with the above findings, the area of the Project where wind turbines can be located has been restricted. This is the area where structural elements of the power plant can be located, including rotors. The area of the development area was determined in accordance with the regulations of the Construction Law and currently amounts to about 94 ^{km2}, while the area within which the actual foundation of wind power plants (the area of development of the power plants (structural elements) and the area of the range of rotor blades) will be possible - about 88 ^{km2}. According to the regulations

of the Construction Law, the development area of power plants should include all their structural elements including rotors, the development area indicated above includes in it the localized foundations of wind power plants and the area covering the width of the rotor radius.

It should be emphasized that, in contrast to the report on the environmental impact of the project[2] performed for the purposes of the proceedings on the decision on environmental conditions, in the course of which the Environmental Decision was issued, the area of the development area is understood as the area inside which all elements of the Project will be located, in the case of wind power plants delimited by the range of rotors, and not only the area that can be used for the foundation of foundations for wind power plants. The consequence of adopting this understanding (as required by the Construction Law) of the development area is a change in the area indicated as the development area in this report compared to the area indicated for the variant approved in the Environmental Decision. The area of development indicatedin the variant determined by the Environmental Decision, and determined taking into account the provisions of the permit for the erection and use of artificial islands, structures and devices in Polish maritime areas issued for the Project (500 m buffer from the border of the farm without development), and also taking into account an additional buffer of 100 m in width (corresponding to the radius of the rotor) was about 89 ^{km2}. The area of development proposed in this environmental amendment proceeding is approximately 88 square ^{kilometers}, while this is the total area including not only the foundations of the wind turbines, but also the above-surface components of the wind turbines, including rotors, and without excluding the area of the safety zones around the wrecks. It should be emphasized that this change is due to the adjustment of the nomenclature to that used under the Construction Law, and it does not result in a real change in the area occupied by all elements of an offshore wind farm.

6. Conditions wind

Wind conditions are described in the Environmental Impact Report, Volume II, Section 1 Project Characteristics, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015, April 2015. In the subject area, the developer made new wind measurements in 2019, on the basis of which the developer decided on the possibility of making changes to the project planned for implementation.

7. Installed power farms

The farm's capacity will range from 720 MW to 1,200 MW. The final output of the farm will depend on the unit power of the generators used. It should be noted that the installed capacity of the farm is not a parameter that affects the type, scale and scope of impacts of the wind farm, unlike the number of power plants, their parameters (height, rotor diameter) and their productivity.

8. Setup power plants

A preliminary spacing of wind farm elements (development plan) has been developed for the Project in the variant selected for implementation, as shown in the figure below.

[2] Offshore wind farm Central Baltic III. Environmental Impact Report, SMDI Doradztwo Inwestycyjne Sp. Z o.o. 2015

Figure 5 Planned spacing of elements of the BIII offshore wind farm in the variant selected for implementation assuming construction of the maximum number of power plants requested (development plan).

	Slupsk Shoal

source: provided by the Contracting Authority

In developing the plan, the results of the following were taken into account: wind measurements and productivity analyses, preliminary geological studies, preliminary technical analyses, previous results of environmental impact assessments performed for the Project and neighboring projects.

The submitted development plan was prepared assuming the installation of the maximum number of power plants requested, i.e. 60 pieces.

The development plan is based on the following key assumptions:

- minimum distances between power plants - 800 m;
- placement of EW in such a way as to ensure the creation of corridors for the safe movement through the farm of vessels, service, rescue units;
- locating an internal marine substation ("MSE") in the central part of the farm;
- laying of internal connection cables along corridors radiating from the MSE to individual power plants, with the cables connecting five to six power plants within a single corridor; laying of an export cable in corridors connecting the internal MSE to the crossing points of the corridor created for the export cable (permission to lay and maintain submarine cables in the exclusive economic zone for the project titled "The MSE. "External connection infrastructure of offshore wind farm Baltic Central III issued by Decision No. MFWK/1/13 dated July 19, 2013 ref. GT7pb/62/14823/decision/2013) with the boundary of the BIII OWF as defined by the PSZW, without crossing the export cable with the internal cables of the farm;
- leaving the area located in the western-northern corner of the farm undeveloped with power plants in such a way as to create an unpaved 5-kilometer-wide corridor undeveloped with power plants, crossing the areas of the OWF Bałtyk Środkowy III and OWF Baltica farms in the SW-NE direction.

The outcome of consultations with the Maritime Search and Rescue Service to ensure safe corridors for passing and transiting maritime rescue units was also taken into account in developing the plan.

It should be emphasized that the presented development plan for the Baltic III OWF may be subject to change (in the case of a decision to build less than 60 number of wind power plants) or further detailing and modification, due to specific requirements to adapt the project to: the selected generators, the geotechnical conditions of the foundation in the places of the planned locations of the farm's elements determined in the full geological campaign, agreements with the competent authorities and institutions of the construction project including, technical expertise in the field of marine safety. However, the key layout assumptions of the farm's components, as defined above, will be maintained.

9. Transmission of electricity generated by farm

The BIII offshore wind farm does not include infrastructure for the transmission of electricity generated by the farm to land. A separate project, the Maritime Electricity Transmission Infrastructure ("MIP"), will be used for this purpose. For the project, a decision was issued by the Regional Director of Environmental Protection in Gdansk dated March 12, 2019, mark: RDOŚ-Gd-

WOO.4211.12.2016.KSZ/AJ.29 on environmental conditions for the implementation of the project to build offshore transmission infrastructure.

The investor also has an agreement on the location and methods of maintaining submarine cables in the Polish exclusiveeconomic zone[3] and a permit to lay and maintain cables in the Polish internal waters and territorial sea[4] and signed a connection agreement with the transmission operator (Polskie Sieci Elektroenergetyczne S.A.) on August 7, 2014.

10. Implementation stages project

As assumed in the project's impact report prepared for the proceedings under which the Environmental Decision was obtained, implementation of the Project may proceed in stages, with the first stage covering up to 720 MW of power. Implementation of the first phase is planned for 2024-2027. Implementation of subsequent phases will depend on investment decisions based on current market conditions. The total construction time for the first phase will be up to 3.5 years. The timing of construction of the next phases will depend on the decision on their size (number of power plants) and available technologies and equipment for the construction of offshore wind farms.

1. Introduction

The section presents an analysis of the variants of the Project, which involves the construction of the Baltic III offshore wind farm in parameters updated from those for which the Environmental Decision was issued. Since this Report is prepared for the purposes of the proceedings to amend the Environmental Decision, thus the Environmental Impact Report[1] - Report 2015, which was the basis for the issuance of the Environmental Decision, provides a reference point both in terms of the basis for comparing alternatives, as well as the principles for conducting an environmental impact assessment. The changes in the description of the Project are primarily related to modifying the parameters of the power plant so that they are in line with the state of the art and the latest solutions offered by technology suppliers. In addition, the changes are due to the progress of design work, including the development of a preliminary plan for the farm and the reduction of the considered foundation technologies for wind turbines. The presented changes in the conditions for implementation and operation of OWF BIII resulting from the Environmental Decision are the subject of both the description of the project and the basis for conducting an impact assessment.

2. Methodology of analysis options

The analysis of variants within the Report consisted in comparing the variant selected for implementation as part of the Environmental Decision (approved variant) and the variant created as a result of changes in the parameters of the Project resulting from the progress of design work, new knowledge that has been accumulated since the issuance of the Environmental Decision, as well as decisions on environmental conditions for other offshore wind farm projects implemented in the vicinity of Slupsk Shoal (variant selected for implementation-WR).

The variant selected for implementation is at the same time the best variant for the environment, and leaving the parameters of the BIII offshore wind farm in the form indicated in the Environmental Decision (approved variant) is a rational alternative (WA) allowed by the Environmental Decision.

The Environmental Decision is a decision that significantly determines the shape of the Project, as well as the scope and schedule of work related to its implementation. The Environmental Decision specifies the environmental boundary parameters.

Both analyzed variants of the Project, which were presented in the Report, are technically feasible, fall within the parameters specified in the permits obtained, and do not pose a threat of significant impacts on the environment, including in particular on the integrity, integrity and subject of protection of Natura 2000 areas, thus fulfilling the requirement for variants in accordance with the provisions of the Act of October 3, 2008 on providing information on the environment and its protection, public participation in environmental protection and environmental impact assessments[2].

[1] Environmental Impact Report, SMDI Investment Advisory, April 2015.
[2] Act of October 3, 2008 on the provision of information on the environment and its protection, public participation in environmental protection and environmental impact assessments (consolidated text Dz.U. of 2020, item 283)

3. Methodology for describing variants

When assessing the environmental impact of a wind farm, it is essential to identify those technical parameters that actually affect the manner and scale of its impacts on the various elements of the ecosystem. In order to make an impact assessment, it is necessary to determine the values of these parameters in such a way as to be able to verify the environmental effects of applying the most far-reaching solutions, which are likely to cause the greatest negative impacts on individual, sensitive environmental elements.

Section 7 of Volume II of the Report presents a matrix of interrelationships of potential emissions and disturbances caused by the OWF, their sources, direct and indirect environmental impacts and the factors determining them, compared with the technological parameters of the furthest-reaching scenario used as the basis for the impact assessment for the BIII OWF in the 2015 Report - NIS 2015 and the proposed updated parameters of the Project approved in the Environmental Decision, and which are the subject of the impact assessment in this Report. As can be seen from this matrix, for an offshore wind farm, the key technical parameters affecting the occurrence and scale of environmental impacts are:

a) Height of structure above water level - possible impact on landscape. It depends on the height of the tower and the length of the rotor radius. The higher, the more far-reaching the impact. It is therefore necessary to determine the maximum amount.

b) Height of clearance between sea level and the lower limit of the rotor zone - possible impact on birds and bats. It depends on the height of the tower and the length of the rotor radius. The smaller it is, the greater the possible impact. It is necessary to determine the minimum height.

c) Rotor diameter - possible impact on birds. It depends on the length of the rotor radius of the generator used. The bigger it is, the greater the impact. It is necessary to determine the maximum diameter.

d) Number of wind turbines and indoor substations - possible impacts on benthic habitats, birds, sediment transport. It depends on wind, technological and economic efficiency. The bigger it is, the greater the impact. It is necessary to specify the maximum number.

e) Total rotor zone - possible impact on birds. It depends on the number of power plants and the diameter of the rotor. The bigger it is, the greater the impact. Specify the maximum size.

f) Occupation of the bottom surface by foundations of power plants and other structures (e.g., substations) - possible impacts on benthic habitats and fish. It depends on the number of power plants and the type of foundation. The larger, the greater the impact. It is necessary to determine the maximum value.

g) Length of cables of internal connection infrastructure - possible impact on benthos, fish, bottom sediments, sediment transport. It depends on the number of power plants, the distance between power plants, the number of internal substations. The greater the overall length, the greater the impact. It is expedient to specify the maximum length.

In addition to the technological parameters specific to the equipment used, some parameters related

to the installation process of the various technologies are important for the environment. Particularly relevant to the scale of impacts of an offshore wind farm at the stage of its construction and decommissioning are the following parameters:

Noise emissions during foundation placement and/or decommissioning - possible impacts on marine mammals, fish, birds. It depends on the type of foundation and the number of power plants. The bigger and longer, the more significant the impact. It is necessary to determine the maximum noise level and the maximum duration of continuous noise emissions at a certain distance from the borders of the farm and/or at the border of areas particularly sensitive to noise impacts.

Length of continuous construction process - possible impacts on birds, marine mammals, fish. The longer the continuous construction time, the greater the scale of impact during the construction phase. It depends on the number of power plants and the type of foundations, as well as the organization of the construction process and supply chain. It is necessary to determine the minimum lengths of interruptions in the continuous duration of construction, understood as the uninterrupted movement of construction units in the area of the farm.

Taking the above into account, the characterization of the different variants of the project will be based on the compilation and comparison of the above-mentioned key boundary parameters for the different technological elements of the offshore wind farm. All technical solutions, considered at this stage, that can be applied within the limiting parameters specified for the various alternatives are presented and described in detail in Section 3 of this Volume.

4. The considered variants of the OWF BIII

4.1. The variant approved through the Decision Environmental Decision

The approved variant, is the most favorable variant according to the Environmental Decision issued. This variant assumes the construction of no more than 120 wind turbines with a maximum rotor diameter of up to 200 meters.

Table 1. Basic parameters of BIII offshore wind farm - DSU approved variant

Parameter	Boundary values
Maximum total height of the power plant above sea level. [m]	275 m
Minimum clearance between the bottom position of the wing and the sea surface [m]	20 m
Maximum rotor diameter [m]	200 m
Maximum number of power plants [pcs.]	120 pcs.
Maximum zone of a single rotor [m2]	31 400 m2
Maximum total rotor area [m2]	3 768 000 m2
Maximum number of foundations of supporting	6

Parameter	Boundary values
infrastructure[3] [pcs]	
Types of power plant foundations considered	Foundations: monopile, tripod, jacket (truss) and gravity foundations
Maximum bottom area occupied by 1 foundation [m^2] (gravity foundation, 50 m diameter)	1 257^{m2}
Considered types of supporting infrastructure foundations	Foundations: monopile, tripod, jacket (truss) and gravity foundations
Maximum bottom area occupied by all foundations [m^2]	158 382^{m2}
Maximum cable length of internal farm connection infrastructure [km]	200 km

Source: DŚU dated July 7, 2016, marked RDOŚ-Gd-WOO.4211.12.2015.KP.22

4.2. The option selected for implementation implementation

The variant chosen by the Investor for implementation is the variant based on turbines of the largest capacity announced for launch in 2024-2027, when the BIII offshore wind farm is planned. These will be 12+ MW class turbines. The project involves the construction of no more than 60 wind turbines.

The rationale for choosing this variant is that it provides the maximum degree of realization of the Project's objective, i.e. the highest efficiency of electricity production, while optimizing costs associated with the construction of a smaller number of power plants, shorter construction time, the need for fewer vessels, construction facilities, and, at the operation stage, fewer maintenance needs. Also, decommissioning a farm with fewer power plants will be less costly. Greater energy production also means achieving a greater environmental effect in terms of fossil fuel substitution and CO2 emission reductions by the energy sector (see Section 14, Volume IV).

Key parameters of the Project that affect the scale and type of environmental impacts are shown in Table 2. In order to determine the limits for the technical parameters of the power plant, the technologies available on the market and the technical conditions of their application were analyzed, including the technological relationships between the various components, such as the rotor - tower - foundation. The maximum capacity of the farm, which was limited in the PSZW to 1,200 MW, was also taken into account.

Table 2. Basic parameters of the BIII offshore wind farm - the variant selected for implementation

Parameter	Option selected for implementation
Maximum total height of the power plant above sea level. [m]	310

[3] Offshore substations

Parameter	Option selected for implementation
Minimum clearance between the bottom position of the wing and the sea surface [m]	20
Maximum rotor diameter [m]	250
Maximum number of power plants [pcs.]	60
Maximum zone of a single rotor [m2]	49088
Maximum total rotor area [m2]	2945244
Maximum number of foundations of supporting infrastructure [pcs]	1
Types of power plant foundations considered	Foundations: monopile and jacket (truss) type
Maximum bottom area occupied by 1 power plant foundation [m2]	79
Considered types of supporting infrastructure foundations	Foundations: monopile, tripod, jacket (truss) and gravity foundations
Maximum bottom area occupied by 1 foundation of supporting infrastructure [m2]	1964
Maximum bottom area occupied by all foundations [m2]	6676
Minimum distance between power plants (counting from the axis of individual structures) [m]	800
Maximum cable length of internal farm connection infrastructure [km]	200

**- the parameter was replaced by the minimum distance between power plants (counting from the axis of each structure)

Source: investor data

The variant selected for implementation is ultimately the same as the most environmentally favorable variant, as it ensures the achievement of the stated business objectives while having the least impact on the environment. Possible modifications and fine-tuning of some technical parameters will take place in the selection of individual technological solutions at the stage of design and contracting of supplies. However, these parameters will not exceed the boundary environmental conditions that were determined for the environmentally most favorable variant.

The changes in the description are primarily related to changes and refinement of some parameters of the variant selected for implementation ("WR"), resulting from technological advances, the progress of design work, including the development of a preliminary plan for the farm area and the selection of foundation technology. It should be noted that the vast majority of the parameters of the project are within the limits specified in the characteristics of the Project, which is an appendix to the

Environmental Decision, with the exception of the total height of the wind power plant, rotor diameter and the maximum area of a single rotor - which results from the assumption of using 12+ class turbines allowing at the same time to significantly reduce the number of power plants without losses in terms of installed power, and the maximum area of the bottom occupied by 1 foundation of the associated infrastructure - this change results from a radical reduction in the number of associated infrastructure from 6 to 1, which, however, is associated with the need to increase the area occupied by a unit foundation for the associated infrastructure. The parameters of the area of the actually buildable surface on which the power plant can be sited are also being changed, but this is not due to actual changes in the scope of the planned project, but to adjust the concepts of the development area so that it is consistent with the concepts used under the Construction Law, and includes all elements of the wind farm, including those above the surface - see also Section 1 of this volume.

4.3. Comparison of the parameters of the different variants variants

The implementation variant ("WR") for the BIII offshore wind farm will consist of the following:

- a maximum of 60 wind power plants of 12 MW+ class, whose basic elements are the foundation, tower, nacelle with power generator and rotor;
- 1 internal marine electrical substation ("MSE");
- submarine power and telecommunications cables, connecting:
    - power plants among themselves (into cable circuits),
    - a group of power plants with an internal marine substation.

The parameters of the proposed variant selected for the BIII OWF, compared with the parameters of the parameters of the Project approved by the Environmental Decision, are presented in the Table below.

Table 3. Parameters of the proposed variant selected for implementation of the BII offshore wind farm, compared with the parameters of the variant approved by the DSU

Parameter	Option selected for implementation- WR	DSU-WA Approved Variant
Maximum total height of the power plant above sea level. [m]	310	275
Minimum clearance between the bottom position of the wing and the sea surface [m]	20	20
Maximum rotor diameter [m]	250	200
Maximum number of power plants [pcs.]	60	120
Maximum zone of a single rotor [^{m2}]	49088	31400

Parameter	Option selected for implementation- WR	DSU-WA Approved Variant
Maximum total rotor area [m^2]	2945244	3768000
Maximum number of foundations of supporting infrastructure [pcs]	1	6
Types of power plant foundations considered	Foundations: monopile and jacket (truss) type	Foundations: monopile, tripod, jacket (truss) and gravity foundations
Maximum bottom area occupied by 1 power plant foundation [m^2]	79	1257
Considered types of supporting infrastructure foundations	Foundations: monopile, tripod, jacket (truss) and gravity foundations	Foundations: monopile, tripod, jacket (truss) and gravity foundations
Maximum bottom area occupied by 1 foundation of supporting infrastructure [m^2]	1964	1257
Highest density of power plants [pcs/km^2]	not applicable*	1.35
Minimum distance between power plants (counting from the axis of individual structures) [m]	800	parameter is not specified in the decision
Maximum bottom area occupied by all foundations [m^2]	6676	158382
Maximum cable length of internal farm connection infrastructure [km]	200	200

* parameter has been replaced by the minimum distance between power plants (counting from the axis of each structure) source: provided by the Employer

In the variant selected for implementation, the use of monopile foundations is planned for all wind turbines in the Project. If it is not technically possible to install this type of foundation for any of the planned power plants, the use of jacket (truss) foundations is envisaged. In the case of an offshore substation, it is not possible at this stage to limit the type of foundations considered. Accordingly, a marine substation can be placed on a foundation: monopile, tripod, jacket (truss) or gravity foundation. The final decision on the foundation method will be made in the construction project, based on verified studies of geotechnical conditions adapted to the selected types of generators and stations. It is important to emphasize the fundamental reduction in the number of foundations for supporting infrastructure from 6 to 1, with the maximum area to be occupied by a foundation for infrastructure being unitarily larger, while the total area to be occupied by foundations for supporting infrastructure is 3.8 times smaller.

Figure 1 below shows the planned spacing of the BIII offshore wind farm elements (development plan)

in the variant selected for implementation.

4.4. Justification of the applicant's proposed variant

The option selected for implementation fulfills the investment objectives of the Project. It allows to achieve a better economic result, by using a smaller number of larger power plants and thus achieve optimal use of the energy potential of the area designated for the construction of the farm, as well as shorten the construction time. At the same time, by reducing the number of power plants, the project's key parameters for the scale of environmental impacts, such as the total rotor zone and seabed occupation, will decrease.

The change that deviates from the conditions set forth in the 2016 environmental decision is the increase in the maximum overall height of the power plant from 275 meters to 310 meters and, which is related to the adoption of the use of modern technological solutions and the implementation of 12+ class turbines. Regardless of the change, the minimum clearance between the lower wing position and the sea surface - 20 m - will be maintained, and the maximum total rotor zone will be changed, ensuring that the impact of the variant selected for implementation will be less than the variant approved through the Environmental Decision (WA).

The most significant difference in the option selected for implementation, compared to the rational alternative, is the reduction in the number of power plants by 50%, i.e. to a maximum of 60 units, compared to the 120 units originally envisioned for implementation, and 70% compared to the furthest-reaching scenario, the 2015 NIS, which forms the basis of the environmental impact assessment in the 2015 Report, assuming up to 200 power plants allowed in the area according to the PSZW.

Reducing the number of power plants and limiting the types of their foundations (monopile and jacket (truss) foundations) in the implementation variant is essential from the point of view of the farm's impacts on key environmental elements, since it is decreasing with it:

the area of the bottom occupied by foundations in relation to the variant approved by the Environmental Decision by about 95.8% , as well as the volume of bottom sediments disturbed during construction and moving with sea currents and the destruction of benthic organisms during installation work, the total area of rotors in relation to the variant approved by the Environmental Decision by about 21.8%, and thus the potential mortality of birds and bats as a result of collisions with working power plants,

the total installation time of the foundations, and thus the period during which underwater noise will be emitted, which can cause hearing damage and scaring (in extreme cases even death) of fish and marine mammals.

Thus, the variant selected for implementation is more environmentally safe than the original implementation variant approved by the Environmental Decision.

1. Introduction

The section presents a description of the technology for the Project, which consists in the construction of an offshore wind farm designated as OWF Baltic Central III in parameters updated in relation to the variant for which the Environmental Decision was issued. Since this Report is prepared for the purposes of the proceedings to amend the Environmental Decision, thus the Environmental Impact Report[1] - Report 2015, which was the basis for the issuance of the Environmental Decision, provides a reference point both for the comparison of alternatives and the basis for conducting the environmental impact assessment. The changes in the project description are primarily related to modifying the parameters of the power plant so that they are in line with the state of the art and the latest solutions offered by technology suppliers. In addition, the changes are due to the progress of design work, including the development of a preliminary plan for the farm and the reduction of the considered foundation technologies for wind turbines. The presented changes - modifications to the parameters of the BIII OWF approved by the Environmental Decision are the subject of both the description of the project and the basis for conducting an impact assessment.

After additional analysis, the variant selected for implementation plans to use monopile foundations for all wind turbines in the Project. If it is not technically possible to install this type of foundation, which may apply only to a portion of the planned power plants, it is envisaged to use jacket (truss) foundations. In the case of an offshore substation, it is not possible at this stage to limit the type of foundations considered. Accordingly, a marine substation can be placed on a foundation: monopile, tripod, jacket (truss) or gravity foundation. The final decision on the foundation method will be made in the construction project, based on verified studies of geotechnical conditions adapted to the selected types of generators and stations.

The above changes did not affect the type of project implementation technology used and will not affect the implementation of the overall project. The description of basic elements is based on the 2015 Report Volume II, Section 3 Description of Technology.

2. Turbines

2.1. Introduction

The selection of the wind turbine model will take place at the stage of preparation of the construction project and will be based primarily on technical and economic criteria, as well as the environmental conditions for the implementation of the project, as indicated in the environmental decision. Technical criteria for turbine selection include, in particular, wind, currents, wave action, sea level, climatic conditions, temperature, ice cover, seabed conditions, as well as the target installed capacity of the farm, the planned spacing of the power plant and existing environmental constraints. Financial criteria are related to, among other things, optimization of production, construction and operation costs of the investment, and risk factors such as quality, acceptability by financial institutions, contractual conditions, conditions of the RES investment support system by the state, etc. The key parameters of offshore wind turbines that affect the scale and type of environmental impacts are rotor diameter, rotor zone, rotor location in space, number of rotors, and thus the total rotor zone and distances between individual rotors.

[1] Environmental Impact Report, SMDI Doradztwo Inwestycyjne Sp. z o.o., April 2015.

2.2. Description technical

A standard wind turbine has a rotor consisting of three blades and a hub located at the front of the nacelle. Inside the nacelle most of the turbine equipment is placed. The rotor is attached to the main shaft supported by bearings. The shaft transfers the energy of rotation through a gearbox to a generator, which converts it into electricity. The transformer, which increases the voltage level before it is sent to the substation, is usually mounted inside the nacelle or at the base of the tower. The wind turbine is mounted on a tower, consisting of steel or concrete pipes with an average diameter of about 8 meters (depending on the model). Helicopter landing pads can be installed on the power plant's nacelles. The power plant's wings rotate at a rate of 4 to 30 times per minute.

A diagram of an offshore wind power plant is shown in the figure below.

The basic parameters of the wind turbines planned for installation at OWF BIII are shown in the table below.

Table 1. Basic technical parameters of wind power plants in the variant selected for implementation

Parameter	Option selected for implementation
Maximum total height of the power plant above sea level. [m]	310
Minimum clearance between the bottom position of the wing and the sea surface[2] [m]	20
Maximum rotor diameter [m]	250
Maximum zone of a single rotor [m^2]	49088

source: provided by the Contracting Authority

[2] Sea surface understood as mean sea level

It should be noted that one or more power plant models with the above parameters can be installed on a single farm. Decisions on this issue will be made at the design stage of each phase of the investment.

Information on the basic materials used in the construction of wind turbines is shown in the table below. It should be noted that the use of particular materials depends on the manufacturer in question.

Table 2. Basic materials used in the construction of wind power plants

Component	Basic materials
Rotor (wings AND hub)	Wings: epoxy, polyester resins, carbon fiber, fiberglass, laminates, composites (under development), metal lightning conductors Hub: cast iron, steel
Gondola	Steel, cast iron, copper, lead, glass reinforced plastics (GRP), epoxy, polyester, fiberglass
Tower	Steel and other materials such as plastics and aluminum used, for example, in ladders, platforms, etc.
Foundations	Steel (monopile, jacket, tripod), concrete (gravity) Steel and aluminum used in connector, access systems, platform, J-tubes, cranes, etc.
Other	About $1^{m3\ of}$ oil in the main gearbox, 0.25 $m3^{of}$ hydraulic oil, 0.02 $m3^{of}$ oil in auxiliary gearboxes and about 1.5 - $2.5^{m3\ of}$ transformer oil Copper, aluminum, plastics for cables and electrical components Paints and coatings Steel

source: provided by the Contracting Authority

2.3. Possible examples turbines

As indicated earlier, the turbine model can be determined only at the stage of the construction project. As wind class I was found in the area of the proposed farm, turbine models that could theoretically be used in the project were selected.

Examples of offshore turbines that were considered in defining the Project's alternatives are shown in the table below. Some of these turbines are already on offer from manufacturers, while others are prototypes in the testing stage. There is also a possibility that other turbine models available during the construction period of the Central Baltic III OWF will be selected for the project.

Table 3 Examples of turbine models likely to be available on the market during the construction period of OWF BIII

Model	Power of a single turbine [MW]	Rotor diameter [m]
MHI Vestas V-164	8.0	164
MHI Vestas V174	9.5	174
Siemens SG 10.0-193 DD	10.0	193
SeaTitan 10 MW	10.0	190
Sway ST10	10.0	164
GE Haliade-X 14	14	220
Siemens 14-236 DD	14	236
Vestas V236-15	15	236

3. Towers

3.1. Introduction

The tower is a component of the power plant, on which a gondola with a rotor and generator is mounted. The tower is mounted on the foundation with a transition piece (connector). The height of the tower depends on the turbine model chosen and local wind conditions. The towers can be made of steel or concrete and consist of several sections that are assembled either at the construction port or at the power plant site. Inside the tower there is a communication line between the platform located on the foundation and the gondola (elevator, ladder), cables are placed to transmit electricity from the generator and other elements necessary for the operation and functioning of the power plant.

The height of the tower, along with the diameter of the rotor, determines two important parameters of a wind turbine that affect the scale of its impacts - the height of the clearance between the bottom edge of the rotor and the sea surface and the total height of the turbine.

3.2. Description technical

The key parameters of the towers are height and diameter. At IMF BIII, towers consisting of steel or concrete pipes up to 175 meters high and with diameters ranging from 20 meters at the base to 4 meters at the top may be used.

4. Foundations

4.1. Introduction

Each of the proposed wind turbines, as well as the offshore transformer station, will be placed on a foundation. There are many types available on the market, the most common of which are:

- monopiles *(monopile foundation);*

- *tripod* type foundations *;*
- jacket *(truss)* type foundations *;*
- *gravity-based structure (GBS)* foundations *;*
- suction *bucket / suction can* foundations - not considered at the site in question;
- *floating foundations (floating foundations)* - not considered at the site in question.

The selection of BIII OWF foundations depends on a number of factors in the area of the planned farm: depth, bottom sediments, geological structure, wave and sea currents, windiness, ice cover and others.

At the current stage of the project, the technical advisor ruled out the use of a suction can foundation, due to the presence of rocks and boulders in part of the project area, and floating foundations - due to the possibility of ice cover and depth. Other types of foundations can be used and are therefore described below. It was assumed at the stage of the Environmental Decision that the final selection of the type of foundation would be made at the stage of the construction project, after taking into account, in particular, such factors as data on the seabed, the depth of the foundation or the dimensions of the selected power plant model, given the geotechnical studies of the subsoil, which will be decisive in the question of foundation selection.

Nevertheless, after additional analysis, the variant selected for implementation plans to use monopile foundations for all wind turbines in the Project. If it is not technically feasible to install this type of foundation, jacket foundations are envisioned for some wind power plants. In the case of the internal marine substation, at this stage there are no plans to limit the type of foundations considered. Accordingly, an indoor marine substation can be placed on a foundation: monopile, tripod, jacket (truss) or gravity foundation. The final decision on the method of foundation will be determined in the construction project, on the basis of verified studies of geotechnical conditions adapted to the selected types of generators and substations, however, it should be emphasized that this applies to the method of foundation in relation to one object in the area of the entire OWF Baltic Central III, which also results from the limitation of the planned number of offshore substations.

The key parameter of foundations, from the point of view of the scale and significance of environmental impacts, is the bottom area occupied by a given foundation. At the construction stage, the critical parameter affecting the magnitude of the environmental impact of foundations is the level and timing of noise emissions associated with foundation placement and the magnitude of the impact on the bottom in the process of preparing for foundation placement. Noise is associated with the driving of the foundation or piles fixing the foundation into the bottom, and the level of emissions will depend on the type of foundation, its diameter, the number of fixing piles and their diameter, and the depth of driving into the bottom. The timing of noise emissions will depend on the number of power plants and the type of foundations. The time required for the installation of the different types of foundations considered is given below, when describing the various technical solutions.

Large amounts of bottom sediment may appear during the implementation of foundation preparation work. These sediments will periodically cause an increase in point sediment agitation. Sediments removed from the bottom during its preparation for the foundation, including gravity foundations, will be managed within the boundaries of the Project area. The sediments will not be moved outside the Project area, but only relocated away from the direct foundation site. If gravity foundations are used, requiring the removal of a significant amount of sediment, it will also be possible to use them to fill (load) the structure of the foundations in question (as ballast) or to shape the bottom near them.

4.2. Monopiles

Monopiles are currently the most commonly used foundations in offshore wind farms. So it is a tried and tested concept, and many companies have experience with these foundations. The advantages of monopiles are fairly simple production, easy transportation, relatively quick installation in the seabed. However, monopiles, due to their relatively large diameter, are subject to high hydrodynamic loads, which can cause damage to the joints inside their structure. Due to their massive steel construction, they are expensive. The monopiles currently in production are also dedicated (and cost-effective) for depths of up to 38 meters, while the BIII offshore wind farm project will be built in an area under development with depths of about 25 to 40 meters. This depth does not preclude the use of new-generation monopiles on part of the BIII OWF surface. In addition, at the current stage of the project, it is permissible to also place a power substation on this type of foundation.

4.2.1. Description technical

The steel monopal is constructed of steel welded cylinders. The length of the monopile can reach 120 meters. Its lower part has an average diameter of 5 - 10 meters and is placed in the seabed at depths of up to several tens of meters. The diameter depends on factors such as turbine size, seabed conditions, and hydrodynamic forces at the site.

The monopal protrudes above the sea surface and is connected to the tower by a transition piece/connector (transition piece), of varying lengths, mounted outside the monopal (the most common solution) or inside. The connection between the monopile and the fastener is usually made with a bonding agent. The connector is initially placed on temporary supports and aligned to a vertical position. The binder is then pumped between the foundation surface and the fastener surface and allowed to solidify. For more information on the use of the binder, see the following section.

Some deformation of the pile may occur during driving. By using a binder, the gaps and stresses created by the aforementioned deformations can be bridged.

The above components can also be bolted together using a flange connection or welded together.

There are also additional elements on the connector, such as the anchorage of service vessels, ladders, an intermediate platform, a working platform, as well as elements of the power infrastructure (flexible cable covers called J-tubes and power and telecommunications cables).

Monopiles require the construction of a layer around them, on the bottom, to prevent leaching, by placing a layer of, for example, stones at the location of the pile in question. It can be laid before or after the pile is driven into the seabed. For more information on the use of a leaching protection layer, see below.

It is also possible to use reinforced concrete monopiles, which are not driven into the bottom, but installed by drilling a suitable hole in the seabed. It is a relatively new technology. Reinforced concrete piles are constructed of prefabricated rings, forming the entire foundation when connected. Its basic parameters are described in the table below, noting that it is not subject to evaluation in the following section of the study (it was not indicated by the technical advisor).

Table 4. Parameters of reinforced concrete monopile foundation

Parameter	Value
Inner diameter (max)	10,5 m
Outer diameter (max)	11,1 m

Length (max)	No data available

4.3. Jacket foundations

Jacket foundations have long been used in the Oil&Gas sector, with large foundation depths (even over 100 m). Therefore, they are dedicated to wind turbines planned for deeper waters (30 - 50 m). Jacket foundations are less sensitive to scour and seabed geotechnical conditions than monopiles, and are lighter and more stable than them. Disadvantages include a relatively high price, more difficult transportation and installation, more complicated construction requiring welding of numerous connections between its components. In addition, at the current stage of the project, it is permissible to also place a power substation on this type of foundation.

4.3.1. Description technical

The jacket-type foundation is constructed of four steel legs connected and reinforced by cross-mounted pipe brackets. Therefore, it is also called a truss foundation. At its top is a connector (transition piece), which allows the foundation to be connected to the power plant tower. These foundations are fixed to the bottom with 4 piles with a diameter of 1.8 - 3 m and a length of up to 70 m. There are also special mats (mud mats) at the bottom of each foundation leg to hold the structure in position on the bottom and prevent settlement of the structure before it is attached to the bottom with piles.

The surface part of the jacket-type foundation also contains additional elements, such as an anchorage area for service vessels, a ladder, an intermediate platform, a working platform, as well as elements of the power infrastructure (J-tubes, cables). A protective layer against leaching is also sometimes used.

4.4. Foundations of the type tripod

Tripod foundations are used relatively infrequently in offshore wind farm projects. They are dedicated to depths of more than 30 m. They are characterized by high rigidity. However, it is a highly stressed structure, and its complex connections are prone to damage. In the case of the project in question, the foundation in question is allowed only for the marine substation.

4.4.1. Description technical

The tripod structure consists of one main member (1st stage), which is the base for the link and tower, and three 2nd stage members, which are the legs of the foundations. The tripod's legs are provided with bushings for attaching piles. There are also special mats (mud mats) at the bottom of each foundation leg to hold the structure in position on the bottom and prevent settlement of the structure before it is attached to the bottom with piles. There are also additional elements on the foundation, such as J-tubes, boat anchorages, transition platform, ladder, etc. A protective layer against leaching is also sometimes used.

4.5. Foundations gravity

Gravity base structure (GBS) foundations are cost-effective at depths of 5 to 40 meters. They can withstand heavy mechanical loads, such as those associated with ice cover, and are relatively inexpensive. The disadvantages of these foundations are the long production cycle (about 3 months) and the relatively large site required. A foundation of this type is being considered for use only potentially as an optional foundation for a substation only.

4.5.1. Description technical

The gravity foundation is a reinforced concrete structure. Its concept is based on using a large mass to support the power plant's structure. The gravity foundation consists of a main shaft and a base. The base can be conical or flat (octagonal, hexagonal, circular, etc.). The foundation can additionally be equipped with a special "apron" (skirt), which can penetrate up to about 5 meters deep into the seabed (depending on substrate conditions) and additionally cause resistance to horizontal movements and reduce scour. The gravity foundation is filled with ballast. During its installation, cement mortar is injected below the base of the foundation to ensure permanent contact between the foundation and the supporting surface. A protective layer against leaching is also used.

5. Internal power lines and telecommunications

5.1. Introduction

The internal power and telecommunications network of the BIII offshore wind farm will consist of submarine cables, connecting:

- power plants ("EW") among themselves (into cable circuits),
- a group of power plants with an internal marine substation ("MSE"),
- internal MSE with an external (which is part of another project) marine substation (optional).

At the current stage, it has been assumed that internal connection cables will be laid along corridors radiating from the MSE to individual power plants, with these cables connecting five to six power plants within a single corridor; the laying of an export cable in corridors connecting the internal MSE to the crossing points of the corridor created for the export cable (permit for laying and maintaining submarine cables in the exclusive economic zone for the project titled "The MSE of the MSE"); and the laying of an export cable in corridors connecting the internal MSE to the crossing points of the corridor created for the export cable. "External connection infrastructure of offshore wind farm Baltic Central III issued by Decision No. MFWK/1/13 dated July 19, 2013 ref. GT7pb/62/14823/decision/2013) with the boundary of the BIII OWF as defined by the PSZW, without crossing the export cable with the internal cables of the farm. The details will be determined only at the stage of the construction project, taking into account the provisions of the environmental decision. A parameter that can affect the magnitude of impacts of the internal connection infrastructure is the total length of the cables.

5.2. Description technical

Connections between EW and MSE will be made using 33 kV or 66 kV cables. Today, 33 kV, three-core cables are most commonly used, consisting of three insulated and shielded copper conductors, in steel wire armament and with additional insulation and an outer protective sheath. Usually, inside the cable, between the conductors, there is a telecommunications cable (optical fiber) for data transmission from the OWF area. If the cable is to be laid in an area characterized by high activity of other users, such as fishing or shipping, which significantly increases the risk of its failure and damage (mechanical damage related to anchoring of ships or hooking and tearing of the cable by fishing gear

used in fishing, such as trawls), cables with additional protective elements, such as additional reinforcement, are used. The 66 kV cable has a similar design, but has a higher transmission capacity compared to a 33 kV cable with the same conductor cross-section. The cross-sectional area of the cables will depend on the operating voltage and cross-section of the working conductor and will be 150 - 180 mm. The weight of such a cable is about 71 Mg/km on average.

The number of power plants included in a single cable circuit will depend on their power and will be determined at the stage of the construction permit. For example, in the case of a 12 MW power plant, it should be no more than 5 power plants. The smaller the number of power plants connected to a single circuit, the lower the risk, resulting from potential cable damage.

Possible interconnections between offshore substations will be made with 110 - 450 kV cables, similar in construction to those described above, with a cross section of up to 300 mm.

The number of cable sections, i.e., the sections between the various elements of the farm, will depend on the number of power plants and substations. Their maximum currently projected length is about 200 kilometers.

5.3. Intersections cables

Seabed surveys carried out for the BIII offshore wind farm have ruled out the presence of linear structures in its area, such as active submarine cables or pipelines. However, the creation of such facilities in the future or the need to cross internal cables belonging to the farm cannot be ruled out.

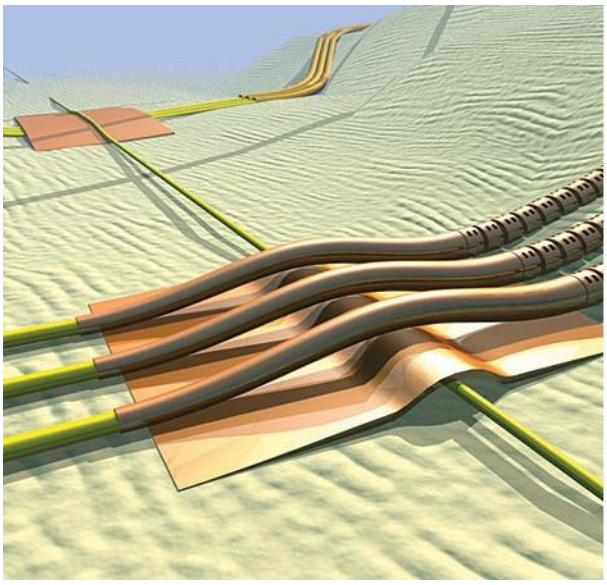
In such cases, safeguards are commonly used to allow collision-free crossing of linear objects on the seabed. There are a great many technical solutions and more are constantly being developed. Among the most popular are:

- precast concrete shoring or mattresses, covering existing linear structures,
- covering existing structures with a layer of stones, either loose or placed in bags,
- plastic safety mats,
- prefabricated steel enclosures,
- special plastic profiles fastened around newly laid cables.

All of the above-mentioned protections are manufactured from environmentally inert and seawater-resistant materials.

Examples of the solutions described above are shown in the drawings and photos below.

Figure 6. Plastic safety mats



Source: publicly available materials www.subseacableprotection.com available as of 09.2020.

Photo 5. Bags filled with stones or gravel

Source: publicly available materials www.sps.gb.com available as of 09.2020.

The above-described protections are laid by means of installation vessels at the previously identified collision points of linear structures. Newly laid cables or pipelines are placed on the protections described above. Such protections can also be used on some sections of internal cables as protection against possible damage, such as ship anchors.

6. Marine substation power station

6.1. Introduction

Electricity generated by EWCs belonging to OWF BIII will be prepared at the farm for further transmission. For this purpose, an internal marine substation ("MSE") will be built in the central part of the farm. The construction of the substation will make it possible to reduce the number of export cables carrying electricity from the wind farm to the land, and will also result in a significant reduction in transmission losses.

Within the BIII offshore wind farm, a substation will be built that performs either a transformer function - receiving*alternate current* (AC) from the wind farms and then changing its voltage (33 or 66 kV) to a correspondingly higher level, allowing its further transmission in alternating-current technology; or a substation combining a transformer function with a converter function (AC/DC) - converting alternating current (AC) to direct current (DC), allowing its further transmission in direct-current technology. At this stage of the project, it has not yet been decided whether energy will be transmitted to the mainland using DC or AC technology. Accordingly, the following section characterizes both technologies and both types of stations.

The internal MSE described in this chapter will be located within the boundaries of the BIII OWF. At the current stage of investment, the approximate location of the MSE has been determined, indicated in Figure 4.

It should be emphasized that the infrastructure for the transmission of energy to land (i.e., offshore and onshore export cables, the onshore substation and possible additional offshore substations is a stand-alone, independent project involving the construction of the Offshore Transmission Infrastructure covered by a separate environmental impact assessment procedure. The information on the MIP contained in this report is only for the purpose of performing an analysis of possible cumulative impacts of the BIII OWF and the MIP. A description of both technologies is included in the chapter on offshore transmission infrastructure.

For the variant adopted for implementation, the construction of one offshore substation was assumed.

6.2. Description technical

6.2.1. Transformer station (AC)

Offshore alternating-voltage (AC) substations are designed to connect power cables transmitting electricity from EW, receive power produced by EW at a voltage level of 33 or 66 kV, increase the voltage level to send it directly to land or to another offshore substation (AC or AC/DC). In addition, control and safety systems will be installed at the station.

The offshore substation (AC or AC/DC) will also serve as an operations center, used during the life of the power plant.

The MSE AC will be built on a platform based on a monopal, jacket, tripod or gravity-type foundation. On the working platform will be installed the necessary power infrastructure, as well as social infrastructure.

Typical MSE AC equipment consists of the following:

- indoor switchgear,
- power transformers,
- mV and HV switchgear,
- chokes and capacitors for reactive power compensation,
- transformers or generators to provide backup power,
- grounding system,
- indoor plant control panel,
- low-voltage distribution equipment for auxiliary equipment and protection of the control and instrumentation system,
- uPS uninterruptible power supply,
- sCADA system devices,
- accommodation of service crews,
- rest rooms and social areas,
- material storage,
- workshop,
- boat harbor,
- helipad,
- safety and emergency equipment, including diesel generators, emergency lighting, and lifeboats.

Cable circuits connecting individual turbines will be connected to the MV switchgear. The standard nominal voltage level of internal cables is 33 kV. Metal, air-insulated or gas-insulated (SF6) switchgear will be used. The medium-voltage switchgear contains circuit breakers, one for each cable circuit, which allow them to be selectively switched off in the event of a disturbance on one of the cable circuits.

Transformers convert voltage from medium (MV) to high (HV) or highest (LV) voltage required by the transmission system. Transformers will most likely be insulated with oil.

The purpose of the HV or LV switchgear is to receive power from the transformers for onward transmission via the export cable, as well as to protect them by allowing one (or all) of them to be shut down in the event of a disturbance, such as an overload or short circuit, or during maintenance. A gas-insulated (SF6) MV or LV switchgear will most likely be used.

The substation can also be used as an installation site for environmental measurement and monitoring equipment, such as meteorological data or wave information.

Photo 6. Offshore substation

source: provided by the Contracting Authority

6.2.2. Converter station (AC/DC)

The marine AC/DC converter station will be built in addition to the transformer station described above, in case the developer decides to use DC transmission. It can be built as a separate facility or as an additional component of the AC substation, which will be the case if such transmission technology is chosen.

Electricity will be sent to the AC/DC converter station from the AC transformer stations. The station's task will be to convert alternating current (AC) to direct current (DC) and possibly raise the voltage in preparation for further transmission to land.

The AC/DC converter station will be built on a platform based on a monopal, jacket, tripod or gravity-type foundation. The necessary power infrastructure will be installed on the work platform, in particular equipment for converting AC to DC power, called "HVDC light" or "HVDC plus" depending on the manufacturer.

Among the main components of the converter station are:

- converter transformers,
- converter thyristors,
- harmonic filters,
- capacitor batteries,
- reactive power compensation chokes,
- external pumping station (cooling system).

It cannot be ruled out that in the future it will be possible to build AC/DC stations with higher capacity, which may at the same time change the parameters given above.

7. Offshore transmission infrastructure (not part of the Project)

The BIII offshore wind farm does not include infrastructure to transmit electricity generated by the farm to land. However, it may cause cumulative impacts with the Project in some areas of the marine part. The parameters of the Offshore Transmission Infrastructure are given on the basis of the Decision on Environmental Conditions dated March 12, 2019, mark: RDOŚ-Gd-WOO.4211.12.2016.KSZ/AJ.29 issued by the Regional Director of Environmental Protection in Gdańsk

"In the marine part, the MIP corridor will be a strip of about 1 km wide. It will begin at the interface between land and sea, about 3 km west of Ustka, and will reach a maximum of 49.5 km north of the coastline. In a section of about 13 km, the corridor will be widened to 2 km for safety reasons. The total length of the corridor is 109 kilometers, and the area is about 123 square kilometers. In the land part, the infrastructure corridor will run through the territories of 2 municipalities: the municipality of Ustka and the municipality of Slupsk, located in Slupsk County, Pomorskie Voivodeship. The underground cable line will cross the above municipalities for about 15 km south of the coastline. Depending on the number of cables to be laid, the width of the corridor at the operational stage can be up to 50 m.

The point of contact between the marine and land parts will be in Modlinek, along 235-238.75 km of the coast.

The MIP will consist of the following:

- In the marine section:
  - Submarine HV or LV cables with the parameters indicated below:
    - Number of cables 19 or 12;
    - Transmission voltage up to 500 kV;
    - Connection capacity of up to 1440 MW;
    - Cable thickness up to 300 mm;
  - Fiber optic lines with a diameter of 17-50 mm, which can be an integral part of submarine cables.
- In the land part:

- Overland MV or LV cables with the parameters indicated below:
  - Number of cables 19 or 12;
  - Transmission voltage up to 500 kV;
  - Connection capacity of up to 1440 MW;
  - The way the cables are laid flat or triangular;
- A land-based GPZ substation with an input voltage of 110 kV/400 kV and an output voltage of 400 kV;
- Possible overhead line of high or highest voltages with a transmission voltage of 110 kV - 500 kV;
- Fiber optic lines (17-50 mm in diameter, either laid next to the cable line trench or suspended from the poles of a possible overhead line)"[3].

Electricity generated in an offshore wind farm can be taken onshore, to the National Electricity System, via high-voltage or highest-voltage submarine cables in either direct current ("HVDC") or alternating current ("HVAC") technology. At this stage, the developer is unable to definitively indicate the technology in which the infrastructure will be built. The decision in this regard will depend primarily on the amount of energy that will need to be brought onshore, i.e. the number and capacity of the farms planned to be connected, as well as economic considerations (e.g. the cost of HVDC and HVAC technologies for a given length of infrastructure, estimated transmission losses for each technology, availability of components, etc.).

Undersea MV or LV cables will be laid using specialized vessels (so-called cable-layers) by sinking into the seabed, usually to a depth of no more than 3 meters (in some sections it may be necessary to sink to a greater depth, for example, due to intensive shipping and the high risk of cables being damaged by ship anchors). The technology and depth of cable laying depends on several factors, including the depth of the water, the type and characteristics of the substrate and environmental conditions. A plowing method using a trailing plow behind the ship from which the cables are fed is indicated for implementation. The cable is inserted by the plow into the created trench directly to the desired depth, and then backfilled with material that has been previously lifted by the plow to create a furrow and falls spontaneously to the bottom by gravitational forces after its passage. Other methods of laying cables, such as using specialized sleds, involve digging the cable into the seabed first (as opposed to the principle of the plow, which creates a furrow into which it simultaneously plunges the cable). In the case of rocky or stony ground, the cable is placed to the desired depth in a groove, which is created using specialized cutting equipment. Laying cables requires anchoring the installation vessel. It is estimated that an average of about 100 - 200 meters of cable can be laid at one anchor position, then the vessel must move and anchor again.

The choice of technology and the location of the landfall of the submarine cables (and in particular its distance from the shore) will depend primarily on the morphodynamic characteristics of the shore at the site of the planned cable landing and the possibility of further routing of the cables in the onshore part. A decision in this regard will be made at a later stage, taking into account the results of environmental studies, including the properties of the ground, which will be carried out in the zone of the planned landing. Typically, steerable drilling technology is used and bentonite-based drilling mud, which is inert to the environment, is used.

[3] Decision on environmental conditions dated March 2, 2019, mark: RDOŚ-Gd-WOO.4211.12.2016.KSZ/AJ.29 issued by the Regional Director of Environmental Protection in Gdansk for the project involving the construction of offshore electricity transmission infrastructure

Depending on the nature of the use of the maritime area through which the MIP route will pass, the depth at which the cables will be laid, the characteristics of the substrate, and the need to cross other existing cables or pipelines, additional protection of transmission cables may be necessary. Nowadays, for example, concrete mattresses or bags filled with cement or sand are used to cover cables, systems of additional cable covers (such as the Uraduct system) and others. Among other things, they provide protection against leaching from the layer of sediment with which the buried cables were covered, as well as additional protection, such as from anchors or fishing gear. Additional protection may be required only on certain sections of the MIP route, those with a higher risk of damage. In sections that cross shipping routes, the cable may need to be buried to a greater depth than on the rest of the MIP route.

Crossing the coastal zone can be done by trenchless methods - such as guided drilling or hydraulic jacking.

8. Progress technology

The characteristics of the project contained in this chapter have been made to the best knowledge of its authors and the Investor. However, the offshore wind industry is growing rapidly. Thus, it is not excluded that technical solutions other than those described will appear at the design stage. In the opinion of the report's authors, they will also be feasible, as long as their main technical parameters are similar to those given in this chapter and their environmental impact is no greater than that described in the report and considered acceptable.

1 Introduction

The section presents the execution stage of the Project, which consists in the construction of an offshore wind farm designated as Bałtyk Środkowy III OWF, with parameters modified in relation to the option for which the Environmental Decision was issued[1]. Since this Report is prepared for the purposes of the procedure for changing the decision on environmental conditions, the Report 2015[2], which was the basis for issuing the Environmental Decision, is a reference point for both the comparison of options and the basis for conducting the environmental impact assessment.

In the case of the option applied for implementation on the basis of the amendment to the Environmental Decision, it should be considered that most of the information contained in the Report 2015 concerning the project implementation phase remains adequate also in the procedure in question concerning the amendment to the Environmental Decision. This results from the fact that admittedly some parameters of the Project change, in particular its parameters related to the number of wind turbines decreasing by 50% compared to the Environmental Decision, some parameters are clarified or specified to the extent allowed by the Environmental Decision, e.g. the foundation method, but the vast majority of parameters remain the same. As a consequence, the specificity of the works carried out at the construction stage described in the Report 2015 does not change, whereas some of the modified parameters of the Project may affect the magnitude of impacts due to the number of planned wind turbines, and which also affects the time necessary to perform individual tasks as part of the construction stage.

After additional analyses, in the option selected for implementation, it is planned to use monopile foundations for all wind turbines within the Project. If it is not technically possible to construct such foundations for any of the planned wind turbines, it is planned to use jacket foundations. In the case of the internal offshore substation, at the current stage it is not possible to limit the type of the considered foundations. In view of it, the internal offshore substation may be founded on a monopile, tripod, jacket (truss) or gravity-base foundation. The final decision on the foundation method will be specified in the building permit design, based on verified surveys of geotechnical conditions adapted to the selected types of generators and substations.

The above changes did not affect the type of the applied technology of project implementation and will not affect the implementation of the entire project. The description of the execution stage was prepared on the basis of the Environmental Impact Assessment Report, Volume II, Chapter 4 Description of the construction process, SMDI Doradztwo Inwestycyjne Sp. z o.o., April 2015.

2 Construction of the wind farm

The implementation of the Project may be carried out in stages, of which the first stage will cover the capacity in the range of 600–720 MW. The first stage is planned for implementation in the years 2024–2027. Implementation of subsequent stages will depend on the investment decisions made based on the current market conditions. The total construction time for the first stage will be up to 3.5 years. The time of construction of subsequent stages will depend on the decision regarding their size (number of wind turbines) and available technologies and equipment for the construction of offshore wind farms.

Opisana sekwencja prac jest powtarzana dla wszystkich elektrowni	This sequence of works is repeated for all wind turbines

2.1 Construction and assembly ports

Prior to commencement of the construction works, the Investor will select the construction and assembly port. It will mainly serve the following tasks:

- unloading of farm components from delivery vessels;
- storage of farm components so as to ensure continuity of deliveries to the installation site during favorable weather conditions;

- installation of nacelles, rotors, towers;
- loading of single elements or partially assembled components onto jack-up vessels or other installation vessels.

The construction and assembly port should meet a number of requirements indicated in the table below.

Table 1. Requirements for the construction and assembly port

General requirements	
Typical terminal area	8 - 38 ha
Quayside length	300 m
Minimum depth	10 m
General requirements	
Clearance	> 10 m
Minimum soil capacity	15-20 Mg/m^2
Office, canteen, amenities	approx. 500 m^2
Separated areas for contractors	+
Accommodation for personnel, locker rooms, parking area	+
Access from the sea	
Availability for service, transport, medium jack-up vessels	+
Availability for large jack-up vessels, cable-laying vessels, large transport vessels	+
Port basin available for vessels with appropriate dimensions (length, width)	150 m, 45 m
Port facilities	
Fuel storage	+
Tugboat services	+
Transshipment services	+
Crane	+
Port infrastructure	
Crane trucks, crawler cranes up to 1,000 Mg	+
No high obstacles, e.g. masts	+

Source: RHDHV technical concept

Based on the above criteria, three potential construction and assembly ports for the BIII OWF can now be indicated. They are presented in the table below. It cannot be excluded that, until the commencement of the construction of the BIII OWF, there will be changes, e.g. alteration of ports, changes in technologies that will enable the use of other ports.

Table 2. Usable construction and assembly ports

Name of the port	Distance from the BIII OWF [km]	Depth [m]
Gdańsk	170	15
Gdynia	170	13
Świnoujście	210	12.8
Ronne Havn (Denmark)	145	8

2.2 Expected types of vessels and vessel traffic

It should be emphasized that the types and traffic of vessels will depend on numerous, currently unknown factors, such as, e.g., the number, type and size of turbines installed at a given stage, manufacturer, availability of construction and service vessels, economic conditions at the construction stage, etc. **Therefore, only approximate data is presented below, based on previous experience in the implementation of similar projects, in order to illustrate the possible scale of the project.** Final assumptions concerning vessel traffic for the BIII OWF may be made at a later stage, when the building permit design is prepared and the final concept of organization at the construction stage is developed. At the same time, it should be emphasized that the reduction of the number of construction and service vessels and the minimization of their stay at sea is one of the main directions of actions aimed at reducing investment costs in the offshore wind energy sector. Larger and larger vessels are being built, which can transport and build an increasing number of wind turbines simultaneously and without the support of additional vessels. Therefore, it should be expected that the values specified below may be reduced and not increased.

It is expected that vessels similar or more modern than those described below will be used for the construction of the BIII OWF. The condition presented and subject to impact assessment in the further part of the report is the worst case scenario as the development of technology will allow the shortening of the construction time and the reduction of pressure on the environment by decreasing the number of construction units. This also applies to potential cumulative impacts with other projects of this type – during their implementation, similar technologies will be used which, as technology advances, have an increasingly smaller impact on the environment.

Table 3. Use of vessels for installation of foundations of one substation

Type of vessel	Operating time per foundation	Engine power	Fuel consumption

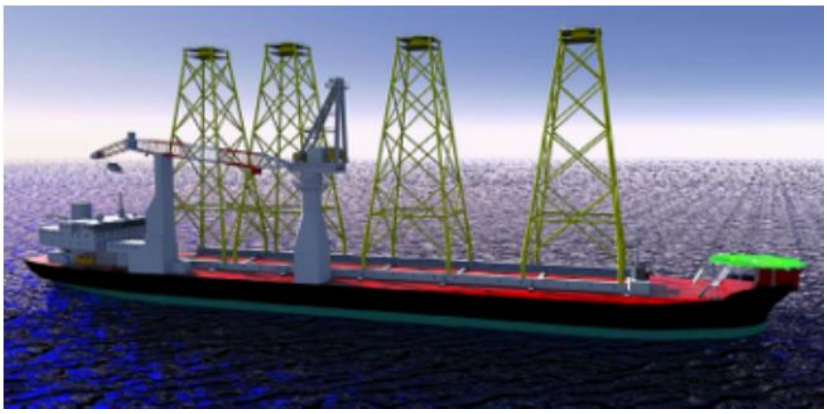
Vessels or jack-up barges are a type of mobile platform consisting of a floating hull equipped with several movable legs to lift the hull above sea level. The jack-up vessel moves independently, while the jack-up barges are transported to the project site by means of tugboats. Once the desired location is reached, the vessel legs are lowered to the seabed, which stabilizes its position. Large jack-up vessels have a lifting capacity of up to 1,200 Mg and 26 m and average dimensions of 150 m (length) x 40 z (width) x 4.5 m (draft).

Photo 1. Jack-up vessel

Source: www.seajacks.com [accessed: March 2022]

Heavy lift vessels can be used for transport as well as (depending on the equipment) for installation of some elements of the farm, e.g. jacket foundations (in the photo).

Photo 2. Large cargo vessel



Source: www.4coffshore.com [accessed: March 2022]

During periods of intensive works, the accommodation of service crews at sea is often used. These may be smaller vessels dedicated to work on wind farms, with the possibility of accommodation of 30 to 100 persons, or larger **hotel vessels**.

Photo 3. Floating hotel used at Borkum Riffgrund 1 & 2 and Gode Wind 1 & 2 farms (Germany)

Source: www.orested.com [accessed: March 2022]

Support vessels will be used for various types of installation works, transportation of equipment, crews, tools, spare parts, etc. These are mostly small fast vessels (25–30 knots), with a capacity of 1–2.5 Mg/up to 12 persons and typical dimensions of 25 m (length) x 6 m (width) x 1.1 m (draft). Single hull vessels, catamarans, SWATH vessels are used in this role.

Photo 4. Support vessel

Source: www.4coffshore.com [accessed: March 2022]

In addition to the above-mentioned basic units, depending on the selected farm components, the following may be used during the construction of the wind farm:

- dredgers used to prepare the seabed for gravity-base foundations (average engine power of 1.5 MW, 200–500 business days),
- barges used for transport of equipment for preparation of the seabed for foundations (average engine power of 1.5 MW, 200–500 business days),
- barges used for removal of excavated material (it is expected that it will be left rather at the project site) (average engine power of 1 MW, 200–400 business days),
- vessel for transport of stones/boulders used to prepare the seabed for gravity-base foundations (average engine power of 6.5 MW, 200–500 business days),
- vessel used for the discharge of stones/boulders at the project site (average engine power 3.7 MW, 200–500 business days),
- pump and generator used for pumping cement binder, e.g. when installing monopiles (average engine power of 1 MW, 100–200 business days),
- barge used for transport of binder and binding equipment (average motor power of 1 MW, 100–200 working days),
- vessel for transport of stones/boulders used for scour protection (average engine power of 6.5 MW, 300–600 business days),
- vessel for the discharge of scour protection stones/boulders (average engine power 3.7 MW, 300–600 business days).

2.3 Transport and installation of farm elements

It is currently impossible to determine the manufacturers of individual elements that may be used in the design. Depending on the place of production, they will be transported either directly to the area of the wind farm location or will be stored in a selected port that will serve the construction of the farm, in the amount necessary to construct a given stage of the project.
Installation of farm elements may take place only under good weather conditions, i.e. slight wave motion. In practice, this means that installation works should be planned for the period from March to October, with waiting periods for the occurrence of favorable weather conditions to be taken into account.

2.3.1 Monopile foundations

Transport and installation of steel monopiles include the following works:

1) transport from the manufacturer or from the place of storage on vessel, barge or by floating (by means of a tugboat);
2) seabed preparation (if necessary);
3) positioning of the installation vessel in the desired position and then properly anchoring or lowering the legs to the seabed (in the case of a vessel or jack-up barge);
4) positioning of the pile by the installation vessel in the vertical position and lowering the pile to the seabed; the pile is partially driven into the seabed under its own weight;
5) placement of the pile at the required depth in the bottom by one of the available methods (hammering, drilling or combination of these techniques), depending on the local, technical and economic conditions;
6) installation of the connector and fastening it on the pile (usually by means of cement binder, bolts or welding);
7) installation of additional elements such as cable shields *(J-tubes),* cables, places of anchoring of boats, intermediate platform, ladder, etc.;
8) placement of a scour protection layer around the pile (this operation can also be performed before driving the pile).

The installation time of one steel monopile is estimated at 2 days, excluding bad weather conditions, of which the time of active pile driving is maximum 6 hours (worst case scenario). The described scope of works is repeated for each foundation.
Sometimes driving piles into the seabed may be difficult due to its design. In this case, in the first place, e.g. drilling may be used, which will enable further installation of the pile using standard methods. It is impossible to determine the duration of drilling at this stage as it will depend on site conditions.
If reinforced concrete monopiles are used, the sequence of works is similar. However, pile driving is not used. It is placed in a vertical position on the bottom and penetrates it to a certain depth under its own mass. Then, the pile is driven into the seabed by drilling, which takes place inside the rings forming the pile. Cuttings are usually left in the project area. As mentioned earlier, this technology is unlikely to be used.

2.3.2 Jacket foundations

Transport and installation of jacket foundations include the following works:

1) transport of the foundation from the manufacturer or from the storage place by means of a vessel or barge; the connector and additional infrastructure (e.g. boat access point) are most often already installed in the shipyard;
2) preparation of the seabed at the place of installation – driving of piles into the seabed with the use of template, which allows their precise location; the piles are driven most often by means of a hydraulic hammer or drilling; a reverse sequence is also possible (i.e. piles are driven after placing the foundation on the seabed);
3) lowering of the foundation to the seabed by means of a jack-up vessel;
4) fixing of the foundation to the piles by means of cement mortar or swelling;
5) possible installation of additional elements such as *J-tubes,* places of anchoring of boats, intermediate platform, ladder;
6) placement of a scour protection layer around the foundation;

The installation time of one jacket foundation is estimated at 4–7 days, excluding bad weather conditions, of which the time of active pile driving is maximum 18 hours (worst case scenario).

2.3.3 Tripod foundations

Transport and installation of tripod foundations include the following works:

1) transport of the foundation from the manufacturer or from the storage place by means of a vessel or barge; the connector and additional infrastructure (e.g. boat access point) are most often already installed in the shipyard;
2) lowering of the foundation to the seabed by means of a jack-up vessel;
3) driving of piles into the seabed through sleeves fixed on the tripod legs; the piles are usually driven using a hydraulic hammer or drilling;
4) fixing of the foundation to the piles by means of cement mortar or swelling;
5) possible installation of additional elements such as J-tubes, places of anchoring of boats, intermediate platform, ladder;
6) piles can also be placed in the seabed before tripod installation using a template; this procedure is similar to the installation of jacket foundation;
7) placement of a scour protection layer around the foundation;

The installation of the tripod foundation lasts on average 4–7 days and may be extended depending on weather conditions, of which the time of active pile driving is maximum 18 hours (worst case scenario).

2.3.4 Gravity-base foundations

Transport and installation of gravity-base foundations include the following works:

1) transport of the foundation from the manufacturer by means of a barge or by floating (by means of a tugboat) (if this is a floating structure) to the project site;
2) preparation of the seabed by removal (e.g. using an underwater excavator) of a layer of light, moving sediments with a depth of approx. 3 m and a width corresponding to the foundation base (up to 50 m), increased by a strip used to lay a scour protection layer, leveling the surface using a suction dredger and then filling this space with stones (gravel) and concrete;
3) lowering of the foundation to the seabed by means of a jack-up vessel;
4) pumping of cement mortar below the foundation base in order to ensure constant contact of the foundation with the load-carrying surface; injection is usually carried out by means of a flexible hose and a pre-installed pipe system;
5) filling of the foundation with ballast by pumping sand into it or ejecting iron rocks/ores from the ballast barge;
6) placement of scour protection materials around the base;
7) connector installation (the wind turbine tower can be connected to the foundation shaft also directly by means of a screw flange);
8) possible installation of additional elements such as *J-tubes,* places of anchoring of boats, intermediate platform, ladders; accessories can be installed onshore or installed on site; cable shields *(J-tubes)* can be installed outside or inside the foundation structure, depending on the design and ballast used.

Unlike other types of foundations, gravity-base foundations require no piling, so their installation is not a source of significant underwater noise.
The time of erection of a single gravity-base foundation is estimated at 4–7 days, excluding breaks caused by bad weather.

2.3.5 Wind turbines

The typical offshore wind turbine construction sequence is presented below:

1) towers and turbines are delivered by land or sea to the port from which the construction will take place;
2) towers and turbines are loaded onto a vessel or a barge and delivered to the project implementation site;
3) the above-mentioned elements can also be delivered directly from the manufacturer to the project implementation site;
4) turbine installation is usually carried out using a jack-up vessel, but other equipment can also be used;
5) turbines and towers are usually delivered to the project implementation site in sections and installed at sea, but it is also the case that these elements are installed onshore and delivered in such a form to the OWF construction site;
6) in the case of installation of individual sections at sea, the first part is mounted on the foundation by means of a connector and subsequent sections are attached to it;
7) the nacelle is mounted on the highest part of the tower;
8) the rotor and blades are lifted and mounted on the main shaft;
9) the process is repeated for each turbine.

Installation of a single turbine takes approx. 2–3 days, excluding bad weather breaks.
Once all turbines are installed and internal MV cables are connected, their tests and technical acceptance are performed. The tests include checking the generator, switchgear, gear box, transformer, cabling, meteorological equipment, turbine control systems, safety systems, etc. This process may take up to 10 days for one wind turbine.

2.3.6 Substations

Substations will be installed in a manner similar to wind turbines:

1) the substation foundation will be transported using an appropriate vessel or barge to the substation placement site;
2) the foundation will be lifted off the vessel and placed on the seabed using a jack-up vessel-mounted crane;
3) the foundation will be installed on the seabed (the installation method will depend on the foundation type);
4) the station platform will be delivered on a transportation vessel or barge, probably with already installed equipment;
5) the platform will be placed using a crane onto the foundation and fixed to the same;
6) the cables will be connected to the corresponding substation equipment (the method is described in the chapter related to cable infrastructure).

However, it is not planned to construct a separate measuring and survey station. Environmental survey equipment will most likely be installed on the substation.
It should be added that new solutions may also be applied in the farm in the form of substations installed on a jack-up platform. Such a platform is floated to the project implementation site and then its legs are lowered onto the seabed and fixed to it.
It should be emphasized that the parameters of the foundations planned to be used for the implementation of the Project are the most important from the point of view of carrying out the environmental impact assessment. It is assumed that the parameters of the AC/DC substation foundations will not exceed the values indicated in Volume II, Chapter 3 of the Report.

In the case of LIDAR measuring stations on floating structures, the installation process depends on the type of support structure, but most often it consists in appropriate anchoring and does not require involvement of large installation vessels, which makes it less sensitive to weather conditions.

Photo 5. Installation of the substation platform on a monopile foundation

Source: www.4coffshore.com, accessed: March 2022

2.3.7 Submarine cables

Submarine power cables are laid using specialized vessels (so-called cable-laying vessels) by sinking the cable into the seabed, usually no more than 3 m deep. At some sections, it may be necessary to lay cables at a greater depth.

The characteristic feature of the cable-laying vessels is the loading surface in the form of a drum, which can accommodate large amounts of submarine cables. Depending on the equipment of the vessels, they shall have one or more places of loading on the deck. When laying the cable, it is discharged into the water from the drum, where the device dragged behind the vessel lays it into the seabed. It is also possible to connect more cables from different drums into systems.

The loading capacity of commonly used cable-laying vessels is several thousand tonnes. For example, 3,900 Mg of 40 to 48 km of a submarine cable can be loaded on the Sea Spider cable-laying vessel, assuming 80 to 100 kg per meter of cable. The Sea Spider vessel is 86 m long and 24 m wide. The draft of the vessel, depending on the load, is 2.00 m to 4.30 m.

Photo 6. Sea Spider cable-laying vessel

Source: www.schottel.de, accessed: March 2022

The cable-laying vessels have special positioning and maneuvering systems that enable them to lay cables in the sea exactly in the desired position. In addition, such vessels have the appropriate lifting technology to manipulate from the deck the devices for laying cables, sinking them into seabed and taking out.

The technology and depth of cable laying depends on several factors, including water depth, type and properties of the substrate and environmental conditions. Submarine cables can be laid directly on or under the seabed at a suitable depth. In the latter case, different devices can be used to create chases in the seabed and to sink the cable; these include:

- **a plow dragged behind a vessel** – the operation principle is similar to that of a conventional plow. The plow is dragged behind the vessel and the plow blade forms a narrow chase in which the cable is laid; everything is done in one operation because the cable is routed inside the plow structure and is laid immediately after a chase is formed. Then, the chase falls in by itself under gravity forces.
- **mass flow excavator** – the chase for laying cables is excavated in the seabed using high-pressure water jets. The excavator (known also as excavating blade) provides fluidization of the material from the substrate along the excavating blade using high-pressure water nozzles and high-pressure water jets flowing out of them. Visually there is no trench, but the substrate becomes boggy. The cable is sinking into it under the influence of its weight. In this manner, the cable may be sunk into the seabed to the desired depth. Sedimentation and compaction processes that occur automatically after the cable laying equipment has completed its work will cause the chase to collapse immediately.
- **cable milling machine** – used in the case of more stable substrate. The laying chase is formed by cutting technology in a similar way as the chain saw works. The cutting and machining elements ensure that the seabed material is transported, and thus a chase for laying the cables is created. At the same time, the cable is laid in the chase at the required depth. Sedimentation processes cause backfilling of the chase after the cable laying equipment has passed. In some cases, it may be necessary to backfill the chase mechanically.

Photo 7. Cable plow

Source: UK Department for Business Enterprise & Regulatory Reform[3]

Photo 8. Mass flow excavator

Source: UK Department for Business Enterprise & Regulatory Reform[4]

The cable-laying equipment can be controlled and powered by the cable connected to the vessel or can be equipped with its own power supply. Special sonar and video technology, as well as monitoring systems, support the control of cable laying, also enabling observation of works carried out underwater.

In order to facilitate the location of the laid cables, a reference marker can be placed on the magnetic reinforcement of the cable during laying in such a way that special instruments can subsequently locate, analyze and accurately determine the location.

If the fiber optic line is not an integral part of the cable, it is laid next to the power cable. Cable laying

[3] Review of cabling techniques and environmental effects applicable to the offshore wind farm industry, 2008.
[4] Review of cabling techniques and environmental effects applicable to the offshore wind farm industry, 2008.

requires the installation vessel to be anchored. It is estimated that on average approx. 100–200 m of cable will be laid on one position of the anchor, then the vessel must move and anchor again.

Burying cables in the seabed is to protect them against the risk of damage, e.g. by vessel anchors and against their movement on the seabed. Moreover, cable burial reduces potential impacts related to the emission of heat and electromagnetic field and radiation.

The standard sequence of laying OWF inner array cables is described below:

1) the cable is usually loaded directly onto the cable-laying vessel at the manufacturer's;
2) the cable is stored on special drums;
3) the cable-laying vessel approaches the foundation of the first wind turbine;
4) the cable is lowered from the vessel and its end is moved closer to the foundation structure using a barge;
5) the cable is pulled through J-tubes installed mostly outside the foundation (with a ROV or by divers) and installed on the first wind turbine;
6) an underwater plow or ROV equipped with a set of cable-laying equipment is dropped from the cable-laying vessel onto the seabed;
7) the plow or ROV lays the cable on the seabed;
8) when the barge reaches another turbine, the cable laying equipment is loaded onto the vessel, and then the cable end is lowered from the vessel and floated towards the next turbine (or offshore substation). The connection of the second turbine is established similarly to the first one;
9) the aforesaid procedure is repeated until all connections are established.

Depending on the specificity of use concerning the offshore area where the cable will be routed, the depth at which the cables will be laid, the properties of the substrate, as well as the need to cut other already existing cables or pipelines, it may be necessary to apply additional cable protection. Currently, e.g. concrete mattresses or bags filled with cement or sand are used to cover cables, systems of additional cable shields (e.g. Uraduct system) and others. They provide, among others, scour protection of the layer of sediments covered by buried cables and additional protection, e.g. against anchors or tools used in fishing. Protections can be used both at the farm construction stage and later if as a result of the cable inspection it turns out that there is such a need.
At the current stage of the project, the final technology of laying submarine cables cannot be indicated. Selection of one or more methods will be made only after determination of cable parameters, detailed identification of substrate properties and other environmental conditions, as well as after selection of the contractor and verification of availability of installation equipment within the selected time frame.

It is estimated that laying one cable section (e.g. between two wind turbines) may take 20–25 hours. However, this will depend on many factors, such as weather conditions, that cannot be predicted at the report stage.

2.3.8 Installation of scour protections

2.3.8.1 Bottom sediment scouring processes

The seabed surface in the BIII OWF area is mainly formed by fine and medium-grained recent sea sands. They constitute the so-called dynamic layer. The thickness of these sediments varies and ranges on average from 0.2 to 3 m.
This seabed structure causes that water flowing through the foundation structure may result in scouring of bottom sediments located around the base. A similar phenomenon may also apply to submarine cables buried in the seabed.
The scale of scouring will also depend on sea currents occurring in the farm area and wave motion. More information on this subject can be found in the chapter presenting the results of seabed surveys (Volume III, Section 3 of the EIAR).

It should be expected that scouring will be limited in most of the farm area mainly to the dynamic sediment layer with a thickness of approx. 3 m.

2.3.8.2 Scour prevention methods

It is possible to apply a number of solutions protecting against scouring of sediments around foundations bases and cables, in particular:

- dumping rocks and gravel (in bulk or in bags) around foundation bases;
- mattresses filled with sand or gravel;
- protective aprons (e.g. in gravity-base foundations);
- flow energy dissipation devices.

The final selection of scour protection methods and the necessity to use them for individual wind turbines will be made at the stage of the building permit design. It will depend on the exact location of a given wind turbine and the seabed conditions prevailing in a given location. In addition, decisions on the source of the rock material and gravel used for erection works will be made at the construction stage by the contractor and will depend, apart from environmental conditions, also on a number of other factors, including technical conditions specified in the building permit design and economic account. It will not be any material from the seabed and will correspond to the normal characteristics of construction materials (products).
Hydrotechnical stone obtained from granite, dolomite, sandstone or basalt rock is commonly used in hydraulic engineering. It is used, among others, in the construction and modernization of breakwaters, coasts, banks and beds of water channels, revetments of the beds and slopes of river channels (as flood protection), ripraps, foundations, as well as port facilities, and yacht and ferry harbors. A good example of using hydrotechnical stone can also be the construction of an artificial reef in Ustka carried out by the Maritime Office in Słupsk. This project protects the beach in Ustka against erosion as a result of sea waves and includes the construction of underwater sills and habitat modules, restoration and construction of a set of groins and alternation of the sea bank. For more information, including photographic and video documentation, please visit the website: of the city of Ustka[5].

It should be noted that all elements of the farm (also cables) will be monitored at the farm operation stage. As a result, additional scouring protection needs may arise, which would not be foreseen earlier, e.g. the need to protect power cables being scoured out of the seabed. In this case, the same methods as described above will be used.

The environmental impact of the scour protection layer consists primarily in increasing the seabed surface from which bottom sediments are removed. The protective materials used are environmentally neutral.

2.3.8.3 Installation of scour protections

Vessels or barges with equipment enabling such an operation are used to lay scour protection materials on the seabed. For this purpose, e.g. pipe systems are used to dump bulky material onto the seabed (sometimes using ROVs) or cranes if the protective material is in bags, for example.

During the placement of the protective layer, the correctness of its placement, including the thickness of the layer, is checked. A sonar, ROV or divers can be used for this purpose.
The thickness of the scour protection layer is 1–2 m. Its maximum width (calculated from the foundation periphery) is presented in the table below.

[5] Source: www.ustka.pl [accessed: March 2022]

Table 16. Maximum width of the scour protection layer

Foundation type	Maximum width of the scour protection layer from the foundation periphery
Monopiles	**20 m**
Jacket foundations	**10 m (around each pile)**
Tripod foundations	**10 m (around each pile)**
Gravity-base foundations	**15 m**

Source: RHDHV technical concept

Decisions on the source of the rock material and gravel used for erection works will be made at the construction stage by the contractor and will depend, apart from environmental conditions, also on a number of other factors, including technical conditions specified in the building permit design and economic account. It will not be any material from the seabed and will correspond to the normal characteristics of construction materials (products). Please note that hydrotechnical stone obtained from granite, dolomite, sandstone or basalt rock is commonly used in hydraulic engineering. It is used, among others, in the construction and modernization of breakwaters, coasts, banks and beds of water channels, revetments of the beds and slopes of river channels (as flood protection), ripraps, foundations, as well as port facilities, and yacht and ferry harbors. A good example of using hydrotechnical stone can be the construction of an artificial reef in Ustka carried out by the Maritime Office in Słupsk. This project protects the beach in Ustka against erosion as a result of sea waves and includes the construction of underwater sills and habitat modules, restoration and construction of a set of groins and alternation of the sea bank.

2.3.8.4 Pointing

The spaces between some elements of the wind turbine structure, in particular between the foundation and the connector, between the piles and the foundation base (jacket, tripod), between the base of the gravity-base foundation and the load-carrying surface can be filled with bonding compounds (binder, sealant). The purpose of using sealant is to connect the two structures and seal the spaces between them.

Due to high stress at the joints, high-strength and low-shrinkage cement binders are usually used to bind offshore wind turbine elements, but other materials can also be used.

Mortar can be transported to the project implementation site by a transport vessel in ready form from shore and may be mixed on board, immediately before the binding operation. Then, the mortar is pumped to the place where binding is performed, e.g. in the case of monopiles – into the space between the pile surface and the connector surface, protected from below with a special gasket preventing excessive amounts of the binder from escaping into the sea. Average quantities of binder used during the installation of offshore wind turbines are presented below.

Table 17. Expected binder consumption during erection of the wind turbine

Foundation type	Binder consumption per foundation
Monopiles	25 m^3
Jacket foundations	50 m^3
Tripod foundations	50 m^3
Gravity-base foundations	125 m^3

2.3.9 Corrosion protection

2.3.9.1 Corrosion phenomenon

Corrosion is a process of destruction of metals and alloys as a result of their reaction with the surroundings (corrosive environment). Metal elements of offshore wind turbines are exposed to corrosion due to aggressive action of seawater, which is electrolyte (water corrosion, electrolytic corrosion).
Corrosive processes result in the destruction of metal, which is observed mainly on surfaces in the form of accumulated solid reaction products such as oxides, rust and scale. If the reaction products fall off from the metallic substrate, roughness of the originally smooth surface or pitting is observed. Corrosive soluble products (metal ions) that contaminate the environment can also form.

2.3.9.2 Corrosion protection methods

In offshore wind turbines, corrosion protection systems are commonly used, most often by means of properly selected **insulation coatings connected to galvanic cathodic protection**. They are used for elements permanently immersed in water, as well as those exposed to water splashing.

Cathodic protection is one of the methods of electrochemical protection consisting in changing the electrode potential of metal in order to prevent or limit its dissolution.

Cathodic protection means that the protected object acts as a cathode in a corrosive galvanic cell. The electrode potential of the protected metal shifts towards negative values, so the oxidation of this metal is limited. Metal is protected by the cathode on which only reduction reactions can take place.

Galvanic cathodic protection, often called sacrificial protection, takes place without any use of an external source of current. The protected object is a cathode of the galvanic cell, the anode of which is a less noble metal (Hg, Zn, Al) to be lost intentionally, called a sacrificial anode. The sacrificial anode dissolves to protect the object to be protected. The protector may be in the form of a coating on protected metal (e.g. galvanized steel) or appropriately arranged anode plates[6].

Anode plates are fixed to foundation structural members, most often by welding. The method of fixing will be specified in the building permit design. The expected required anode mass for individual foundation types is indicated in the table below. Once installed, anodes are most often sufficient for the entire lifetime of the farm.

Table 18. Expected required mass of zinc or aluminum anode plates for individual types of foundations

Foundation type	Expected required anode mass per foundation
Monopiles with additional protective coating	**Approx. 6 Mg Al-In-Zn anodic material, including 5% Zn**
Monopiles without additional protective coating	**Approx. 13 Mg Al-In-Zn anodic material, including 5% Zn**
Jacket foundations with additional protective coating	**Approx. 7.5 Mg Al-In-Zn anodic material, including 5% Zn**
Jacket foundations without additional protective coating	**Approx. 22.5 Mg Al-In-Zn anodic material, including 5% Zn**
Tripod/quadropod foundations with additional protective coating	**Approx. 10.7 Mg Al-In-Zn anodic material, including 5% Zn**

2.4 Safety zones

Safety zones will most likely be created around OWF elements (wind turbines, substation under construction, etc.), with limited access of vessels not belonging to the farm operator. The creation of such a zone is aimed at reducing the risk of their collision with farm facilities and, consequently, hazard to human health and life, environmental pollution (including with hazardous substances) and major material losses. The range of possible safety zones and the rules of movement in these zones will be determined at a later stage of the project.

The decision on establishing a safety zone in the area of the wind farm is made by the director of the competent maritime office on the basis of the provisions of the Act of March 21, 1991 on maritime areas of the Republic of Poland and maritime administration (consolidated text: Journal of Laws of 2020, item 2135). A possible need to indicate any limitations in the scope of making the farm area available during the construction in the decision on environmental conditions may be indicated by the competent Maritime Office during arrangements as part of the environmental impact assessment.

Moreover, the issues of limiting access for fishermen and other users of the BIII OWF area are the subject of consultations between the Investor and interested groups and the Maritime Office.

2.5 Obstacle marking and warning systems

Wind turbines, substations and possibly other farm facilities under construction will be properly painted, illuminated and equipped with warning systems, in accordance with the requirements of Polish aviation and maritime regulations. More relevant information is presented in Section 11 of Volume IV containing an assessment of the impact on other sea users, including maritime navigation and aviation.

3 Emissions during the OWF construction stage

The anticipated time necessary to build the BIII OWF is approx. 3.5 years, with the farm construction process divided into at least 2 stages separated by several years. The construction cycle time for each of the stages will therefore be shorter and it is unlikely to exceed 2 years. The construction time, and in particular uninterrupted activity of construction vessels in the farm area, will depend on many factors, mainly on planning and efficient management of the supply chain of individual elements of the farm, financing schedule, delivery dates of equipment, availability of specialized equipment used for their construction, and above all weather conditions, etc. The conditions indicated in the environmental decision may also affect the construction period. Therefore, it should be taken into account that the emissions described in this section will be spread over time and, at this stage, it is not possible to determine the exact time of occurrence of individual emissions.

In the option being the subject of this Report, approx. 70% less wind turbines will be built than planned in the set of parameters being the worst case scenario – WCS 2015 and twice less than specified in the Environmental Decision.

Individual stages of the Project implementation will be carried out in shorter periods than those assumed in the Report 2015, thus it should be considered that the Project will cause lower impacts during the implementation phase both than those constituting the basis for conducting the impact assessment in the Report 2015 and described by the set of parameters being the worst case scenario – WCS 2015, as well as from the option approved by the Environmental Decision.

3.1 Manufacturing of wind farm elements

The manufacturing of elements and subassemblies at this stage will take place in manufacturing shipyards and other onshore plants.

Emissions generated in the process of manufacturing of wind farm elements are not assessed in this report. The manufacturing of wind farm elements is carried out in manufacturing plants whose construction and manufacturing processes are subject to separate environmental impact assessment procedures and relevant environmental protection regulations appropriate for the location of a given plant.

Table 19. Emissions related to the manufacturing of wind farm elements

Emissions related to the manufacturing of wind farm elements	
Potential emissions and environmental disturbances	• use of environmental resources for manufacturing (increase in demand for energy, raw materials and structural materials) • noise emission • emission of pollution into the atmosphere • water abstraction • wastewater generation • waste generation
Emission sources	Manufacturing machinery and equipment Means of transport:
Emission range	Area of a manufacturing shipyard, adjacent areas (if any)
Frequency of emission occurrence	Repeatable (during construction)
Duration of emission	Duration of construction and approx. 1 year before its commencement
Reversibility of emission	Reversible

Probability of occurrence	Very high
Preventive, minimizing or mitigation measures	Manufacturing plants must operate and operate in accordance with the applicable environmental regulations. Manufacturing should be carried out in accordance with the applicable environmental standards (e.g. emission of pollutants into the atmosphere or water, waste storage, etc.). Preventive, minimizing or mitigation measures will be taken depending on the existing needs in this respect.
Additional notes	Emissions generated in the process of manufacturing of wind farm elements are not assessed in this report. It is the liability of manufacturers, not the Investor of the BII OWF.

Source: RHDHV technical concept, own materials

3.2 Sea transport of wind farm elements to the construction and assembly port

The Investor will select the manufacturers of individual OWF elements not sooner than at the stage of the building permit design. Therefore, at the stage of preparation of the EIAR, it is not possible to provide any information on this transport. In the worst case scenario, components of most wind farm facilities will be transported by sea. This is the most likely scenario.

Table 20. Emissions related to sea transport of wind farm elements to the construction and assembly port

Emissions related to sea transport of wind farm elements to the construction and assembly port	
Potential emissions and environmental disturbances	• increased vessel traffic • noise emission • emission of pollutants into the atmosphere • wastewater generation • waste generation
Emission sources	Vessels (ships, barges, etc.)

3.10 Transport, recovery or neutralization of waste and wastewater from vessels

3.12 Expected level of pollutant emission into the air

Vessel traffic (at each stage of the project) will involve emission of pollutants into the air, with average levels as follows:

- NOx: 20–50 kg/m^3 of fuel,
- PM10: 1–2.6 kg/m^3 of fuel,
- SO2: 1.7–17 kg/m^3 of fuel.

3.13 Expected level of underwater noise emission

Sound can be generated during all stages related to the construction, operation and decommissioning of the offshore wind farm. The greatest concern is, however, related to underwater noise emitted during the construction due to high sound levels generated when driving piles into the seabed (piling). Forms of marine life such as fish or marine mammals are sensitive to sound, and therefore the noise accompanying activities related to the construction of wind farms may affect them at significant distances. Wind farm construction methods differ for specific projects, and thus generate sounds with different characteristics into the marine environment.

In the area of the Project, several models of underwater noise propagation related to the installation of foundations of the offshore wind farm have been carried out in recent years. The results of these modeling were presented in the environmental impact assessment reports for the BSIII OWF project (SMDI 2015a), BSII OWF project (SMDI 2015b) and Baltica OWF project (IMG/MEWO 2017).

In all studies, the use of a monopile foundation driven into the seabed was assumed as the worst case scenario generating the highest ranges of sound propagation. The modeling performed at the location in question for the purposes of the Report 2015 assumed the use of a foundation with a maximum diameter of 10 m, and for the Bałtyk Środkowy II and Baltica farms – 12.5 m. Currently, for the BIII OWF, it is also assumed to use a monopile foundation with a maximum diameter of 10 m (see Volume I Chapter 3). For the purposes of the submitted report, noise propagation modeling was repeated – “Sound Simulation Pile Driving for Baltyk WF- Baltyk II; Baltyk III, pile driving noise modeling”.

Based on the directions of noise propagation specified in the modeling for the BIII OWF, as well as the maximum ranges for the monopile with the diameter of 12.5 m (BII OWF), the noise impact zones on marine mammals (seals and porpoises) and fish occurring in the BIII area, in which bodily injury, temporary threshold shift and behavioral reaction consisting in avoidance may occur, were estimated. Directions and ranges of impacts so determined were subject to comparative verification on the basis of results obtained for the project directly adjacent to BIII – Baltica OWF. The assessment also used the results of modeling of cumulative impacts for the case of parallel piling on BIII OWF and Baltica OWF farms (SMDI 2015a, MIG/MEWO 2017). It should be emphasized that the said modeling was performed assuming similar geological conditions prevailing in the aforementioned areas of individual projects (boulder clays with sand and gravel cover). Therefore, this chapter constitutes the technical basis for the EIA for marine mammals and fish in this respect.

Noise propagation directions

Modeling results indicate that sound transmission is highly frequency-dependent, where higher frequencies (i.e. above 2 kHz) are attenuated much faster than low frequency sounds. Attenuation was also bathymetry dependent, which results in differences in the direction of sound intensity – sound levels are lower towards the Puck Bay, the Słupsk Bank and the South Middle Bank, mainly caused by shallowing in these directions. Sound propagates to the greatest distances in the NW and NE directions (see **Error! The reference source cannot be found**.).

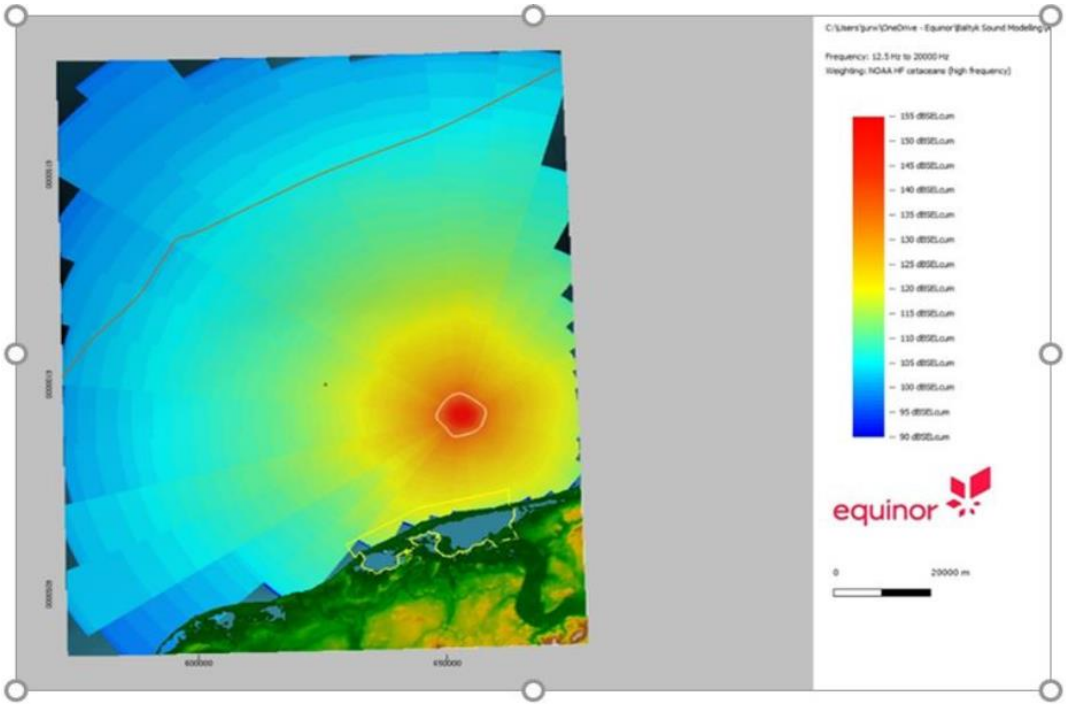
For the purpose of preparing the submitted Report, a repeated modeling of noise propagation was performed for the installation of monopile foundations with a diameter of 10.0 m.
The dBSea tool (Irwin Carr Consulting) was used to model sound propagation. This tool can be used to model sound propagation within the full range. It also offers several mathematical solutions (solvers) for modeling sound propagation. For frequencies lower than 400 Hz, a solver using parabolic wave equation was applied. For frequencies above 400 Hz, a solver with a ray-tracer was applied.

The dBSea tool (Irwin Carr Consulting) was used to model sound propagation. This tool can be used to model sound propagation within the full range. It also offers several mathematical solutions (solvers) for modeling sound propagation. For frequencies lower than 400 Hz, a solver using parabolic wave equation was applied. For frequencies above 400 Hz, a solver with a ray-tracer was applied.
The results were calculated along 36 radial slices (10 degrees per slice). Along each slice, sound properties were calculated at a distance of 60 m (2400 range points). The depth resolution was 2 m. For the graphical display, the calculated results were displayed/extrapolated using a 60 m resolution mesh. To calculate and display the range distance, the highest values found at the projection point on the surface were used.
Sound sources were introduced into the propagation model as spot sources at half of the water depth, i.e. 13 m for Bałtyk III WTG60.
With the application/introduction of a damping effect of one bubble curtain and appropriate reduction of SEL and SPL at source, it resulted in a situation where none of the threshold values was exceeded at the boundary of the Słowińska Refuge Natura 2000 site (Figure 5 and Figure 6 – the results of modeling with and without the use of a bubble curtain are presented in Chapter 9 of this Volume of the Report).

Figure 6 Bałtyk III monopile with a diameter of 10 m, 4,500 kJ reduced by 11 dB with the use of a bubble curtain, SELcum 16,800 m impacts; the white line indicates the TTS level of 140 dB for whale VHFs. The yellow line indicates the boundary of the Słowińska Refuge Natura 2000 site and the boundary of the Polish EEZ is marked with the brown line.



Source: provided by the Employer

Sound propagation modeling involves some uncertainty and the determination of impact zones with a numerical resolution of one meter is not an indicator of the total accuracy and precision of the results. However, the results of the model study indicate that none of the threshold values of potential impact on

porpoises and seals (TTS, PST) will be exceeded at the boundary of the Słowińska Refuge Natura 2000 site if mitigation techniques are applied. Model calculations showed that one bubble curtain would be sufficient to achieve the desired results. The hammer energy of 4,500 kJ can also be seen as the worst case scenario, and therefore additional mitigation measures can be achieved by using less hammer energy, if possible.

Range of impact

The following were considered as impacts related to underwater noise emission caused by driving foundations into the seabed:

- Permanent Threshold Shift (PTS);
- Temporary Threshold Shift (TTS);
- behavioral response (avoidance).

In order to determine the zones of potential impact, various types of noise exposure criteria were used both for marine mammals and fish, on the basis of which the average and maximum distances for sound levels high enough to meet the given criteria were calculated. Most of them come from an extensive publication by Southall et al., 2007 (more on the sensitivity of marine mammals and fish to noise impacts can be found in Volume IV. Chapter 4 and Chapter 6 of the EIAR).

The determination of potential impact zones took into account the results of modeling with the use of mitigation measures against noise propagation in the form of a bubble curtain or other measure of no lesser degree of noise propagation reduction. The use of such actions as a mandatory recommendation is included in the conclusions of the Report.

The impact zones were determined in accordance with the precautionary principle, taking into account the worst result from the modeling carried out in the project implementation area – see Table 30.

Table 30. Zones of potential impacts on marine mammals and fish caused by noise emission during piling of the monopile foundation (based on SMDI 2015a, SMDI 2015b, IMG/MEWO 2017)

Impact	Maximum threshold range (cumulated strokes when driving 1 foundation for 1 hour) [km]		
	BII	BIII	Baltica 3
Porpoise PTS [SEL 155 dB re 1 µPa^{2}s]	0.8	0.4	9.4
Porpoise TTS [SEL 140 dB re 1 µPa^{2}s]	5.6	3.5	26.3
Porpoise avoidance [SEL 140 dB re 1 µPa²s]	32.4	15.7	46
Seals PTS [SEL 185 dB re 1 µPa^{2}s]	5.1	1.2	0.8
Seals TTS [SEL 170 dB re 1 µPa^{2}s]	29.7	20.7	6.7
Seals avoidance*	29.7*	20.7*	6.7*
Fish PTS [SEL 203–216 dB re 1 µPa^{2}s]	0.7	0.3	1
Fish TTS	**14.7**	5	9.2

[SEL 186 dB re 1 μPa^{2}s]			
Fish avoidance [SEL 135-142 dB re 1 μPa^{2}s]	32.4	15.7	**32.6**

*the avoidance zone for seals was determined on the basis of the latest literature – see below.

Many studies to date have shown that behavioral reactions of seals, such as avoidance reaction, are rare. This statement is consistent with the observations of harbor seals and gray seals which did not react to the noise related to the structure in places of their rest and are known for fast habituation capabilities, even at relatively high levels of sound intensity (Edrén et al., 2010). However, the studies from recent years show that gray seals react to sonar signals (with a frequency of 200 and 375 kHz), remaining longer above the water surface (at 200 kHz) or avoiding a given area (at 375 kHz) (Hastie et al., 2014). Southall et al. (2007) suggests applying a behavioral reaction criterion based on TTS values; this criterion was adopted in this report.

For seals ((Southall et al., 2007) indicates a PTS limit equal to 218 dB re 1 μPa peak (186 dB re 1 μPa^{2}s SEL), and a TTS limit of 212 dB re 1 μPa (171 dB re 1 μPa^{2}s SEL) underwater. TTS for the harbor seal exposed to sound for a longer period was examined by (Kastelein et al., 2012). TTS of approx. 6 dB was achieved after 60 minutes of exposure of the animal to sound with a one octave bandwidth, with a center frequency of approx. 4 kHz at the intensity equal to 136 dB re 1 μPa.

3.14 Expected level of sediment agitation and redeposition

The worst case scenario constituting the basis for the impact assessment in the Report 2015, i.e. WCS 2015, in the context of impacts relating to disturbance of bottom sediments and their distribution and restoring, was the installation of 200 gravity-base foundations in the reasonable alternative option. Assuming such a scenario as the worst case scenario was related to the necessity to precede the installation of such foundations with dredging works. It is assumed in the Report 2015 that, for the purpose of installation of a single gravity-base foundation, the seabed would require to be dredged at a diameter of up to 70 m and a depth of up to 3 m, which would result in significant agitation of bottom sediments. The expected ranges and level of sediment disturbance and its subsequent restoring in connection with the construction of the BIII OWF in the worst case scenario are presented in Appendix A to the Report.

In the currently requested option selected for implementation, in relation to wind turbines, the use of gravity-base foundations was excluded, whereas this type of foundation may be used for the purposes of construction of an internal offshore substation. In this option indicated for implementation in this procedure, wind turbines can be founded in the BIII OWF development area only on monopile and jacket foundations. Installation of these types of foundations does not require prior preparation of the seabed (dredging), which is necessary in the case of gravity-base foundations. The related disturbance of the seabed will occur mainly during the setting (driving) of foundation piles, foundation of jacket structures and laying of scour protection layers. These activities may cause the disturbance of bottom sediments in the direct vicinity of the place of works, whereas the amount of removed sediments will be incomparably lower than in the case of seabed dredging for the purpose of installation of gravity-base foundations. In turn, this will result in a dramatic reduction of potential emissions of pollutants and biogenic substances that may be released from agitated sediments.

At the construction stage, during laying cables between wind turbines in the seabed and during preparation of the seabed for installation of foundations (if gravity-base foundations are used), sediments deposited on the seabed will be agitated. Sediments will also be uplifted into the water column during the laying of the export cable from the location of the offshore substation. The agitated sediment will form, for some time, suspended matter in the water column, which will move in accordance with sea currents at short distances, and then the sediment will reach again on the seabed, in another place (sediment redeposition).

The formation of suspended matter in the water column will cause changes in water quality, and thus secondary impacts on aquatic organisms. However, sediment fallout may affect benthic organisms as well as fish eggs and larvae. Potential impacts on living organisms, sediment structure and water quality are described in Volume IV of the Report.

The displacement of sediments during the construction of the wind farm depends primarily on the volume of sediments stirred during the works (e.g. monopile foundations do not require any dredging works). The selection of gravity-base foundations results in an increase in the volume of sediments removed as part of dredging, and thus in an increase in the rate of sediment drift. Approximately 70% less foundations will be built in the option which is the subject of this Report than envisaged for the set of Project parameters representing the most worst case scenario – WCS 2015, and twice less than specified in the Environmental Decision. The use of gravity-base foundations for the wind turbines was excluded, so the bottom sediment structure will be disturbed over a correspondingly smaller area.

In view of the above, the impacts relating to the disturbance and subsequent restoring of sediments connected with the installation of foundations for wind turbines in the option approved by the Environmental Decision, both direct (such as an increase in the suspended matter content in water resulting in a reduction in its transparency) and indirect (such as a change in the living conditions of marine organisms, e.g. backfilling of benthic organisms) will occur only on a local scale. The intensity and size of the expected impacts will be incomparably lower than in the case of installation of gravity-base foundations. Impacts associated with the installation of the gravity-base foundation may occur only in relation to the internal substation (if such a foundation is selected). Due to the planned location of the substation in the central part of the OWF area, it is not expected that they may extend beyond this area.

Due to the reduction in the number of foundations planned for installation in the option selected for implementation, the number of locations where the bottom sediments will be disturbed, in connection with anchoring of vessels involved in the construction of the farm, will also be limited. Since the expected maximum length of the cable infrastructure in the option selected for implementation has not changed, the scale of sediment disturbance relating to its installation described in the Report remains unchanged.

3.15 Expected level of emissions of pollutants from sediments

The agitation (disturbance) of the bottom sediments related to the construction (placement) of foundations for the farm facilities, anchoring of vessels or burying of the cable is a process which favors the transfer of pollutants from the sediments to the water column (Uścinowicz, 2011; Bojakowska, 2001; Frostner, 1980; Bourg and Loch, 1995; Dembska, 2003).
In this way, it can be penetrated by the following:

- pollutants, including heavy metals as well as PAHs and PCBs;
- biogenic elements – nitrogen and phosphorus.

The phenomenon of depletion of the sediment surface layer in places of sediment agitation is confirmed by scientific research. This process was observed by Bolałek and Pustelnikovas (1995) in the Port of Klaipėda at the point of return of hydrofoil crafts and vessels, as well as by Protasowicki et al. (1992) during surveys of the bottom sediments of the waterway in the Szczecin Lagoon.

The most unfavorable situation may occur in the case of sediments featuring an increased content of harmful and biogenic substances, and a large number of fine fractions (clayey and silty fractions). In this case, the water quality may deteriorate significantly as a result of an increase in the concentration of harmful and biogenic substances (as a result of transfer from the sediments to the water column as a result of sediment stirring processes). These sediments will also contribute to the formation of a larger amount of suspended matter, which will remain in the water column for a long time. Intensive resuspension may cause the release of biogenic substances immobilized in the sediment and contribute to eutrophication.

In the case of sandy sediments with a small content of organic matter (e.g. coarse sandy sediments), the described processes will be less intensive. These sediments are generally characterized by a small amount of fine-grained fractions and a low concentration of metals and persistent organic pollutants.

The worst case scenario constituting the basis for the impact assessment in the Report 2015, i.e. the WCS 2015, in the context of releasing metals, pollutants and biogenic substances from sediments into the water column, was the use of gravity-base foundations with a diameter of 50 m during the implementation of the Project. Their construction requires preparation of the seabed, which involves the removal of the bottom sediment layer, not only in the foundation placement area, but also in its direct vicinity. Given the above, in the Report 2015, it was assumed that in the worst case scenario, a sediment layer with a depth of 3 m and

a diameter of 70 m (50 m of the foundation diameter + 20 m strip from the protective layer) will be removed, which gives 11,545 m^3 of agitated sediments per foundation. Approximately 70% less foundations will be built in the option which is the subject of this Report than in the worst case scenario – WCS 2015, and twice less than specified in the Environmental Decision. The use of gravity-base foundations for the wind turbines was excluded, so the bottom sediment structure will be disturbed over a correspondingly smaller area.

For other technologies analyzed (monopile, tripod, jacket), the volume of disturbed sediments will be many times smaller, which is related to the fact that they do not require seabed preparation in most cases, as well as to the fact that the diameter of the foundation piles driven will be many times smaller than the diameter of gravity-base foundation. The sediments around the piles driven will liquefy as a result of vibrations caused by the operation of the pneumatic hammer.
Additionally, regardless of the type of foundation selected, the sediments will be stirred during cable laying. The width of the cable trench is approx. 1.5 m, average depth – up to 1.5 m, length – up to 200 km, which gives a total of 450,000 m^3 of stirred sediments (for the entire inner array cable network).

Moreover, during the placement of foundations and installation of towers, stirring of the bottom sediments will be observed due to anchoring of vessels. The anchoring process itself is short-term, covers a small area (spot process), and will be conducted at a depth of approx. 3 m, so the volume of sediments disturbed will also be small. Also in this case, due to the reduced number of wind turbines, i.e. by 50% in relation to the Environmental Decision and 70% in relation to the WCS 2015, the number of necessary vessel anchoring operations will be significantly reduced.

3.16 Expected level of emission of Al released to the environment in the case of monopile foundations

For offshore structures, primary Al-based anodes are used for cathodic galvanic protection, which, depending on the specific alloy, manufacturer and applied standard, also contain Zn (2.5–5.75%) and In (0.015–0.04%). The amount of anodic material necessary to protect offshore wind farm steel structures against corrosion depends primarily on the type of foundations (their surface), planned service life (e.g. at least 25 years), sea water conditions, arrangement of anodes and possible application of additional methods of anticorrosive protection, e.g. epoxy resin or polyurethane coatings. Chemical emissions are similar to the amount of anodic material used, assuming that its predominant part will be “used” during 25 years of operation and will enter the marine environment (Kirchgeorg et al., 2018). Simplified calculations of the necessary amounts of Al-Zn-In anodic material made on the basis of the DNVGL-RP-B401 (2017) standard by Kirchgeorg et al. (2018) were used to estimate potential Al and Zn emissions relating to the Project for various foundation structures used in offshore wind farms, in the option with and without additional coating. According to these calculations, for foundations without additional coating, the required amount of anodic material ranges from 13.0 Mg (monopile) to 32.0 Mg (tripod), whereas the additional coating causes its significant reduction to 6.0 and 10.7 Mg, respectively. It should be noted that the indicated calculations do not include additional factors, such as the distribution of anodes over the entire structure, which must be taken into account when designing the anticorrosive protection and which may change the total required number of anodes. The results of estimation of the expected emissions from anticorrosive protection for the Project are presented in the table below.

Table 31 Al and Zn amounts that may potentially be released to the environment during 25 years of operation of the Project as a result of application of the galvanic cathodic protection against corrosion, assuming 5% of Zn content in the Al-Zn-In anodic material in the worst case scenario.

Foundation type	Additional protective coating	Weight of the Al-In-Zn anodic material, including 5% Zn [Mg]	Amount of released Al and Zn	
			1 foundation, the amount of element released during the entire operation of the farm (25 years)	Worst case scenario (200 foundations), amount of released element per year by the entire farm

Monopile	no	approx. 13.0	approx. 12.35 Mg Al approx. 0.65 Mg Zn	approx. 98.8 Mg Al approx. 5.2 Mg Zn
	yes	approx. 6.0	approx. 5.70 Mg Al approx. 0.30 Mg Zn	approx. 45.6 Mg Al approx. 2.4 Mg Zn
Jacket	no	approx. 22.5	approx. 21.38 Mg Al approx. 1.13 Mg Zn	approx. 171.04 Mg Al approx. 9.04 Mg Zn
	yes	approx. 7.5	approx. 7.13 Mg Al approx. 0.38 Mg Zn	approx. 57.04 Mg Al approx. 3.04 Mg Zn
Tripod	no	approx. 32.0	approx. 30.40 Mg Al approx. 1.60 Mg Zn	approx. 243.2 Mg Al approx. 12.8 Mg Zn
	yes	approx. 10.7	approx. 10.17 Mg Al approx. 0.54 Mg Zn	approx. 81.36 Mg Al approx. 4.32 Mg Zn

Source: own study based on Kirchgeorg et al. (2018).

The prepared estimation shows that the highest annual Al and Zn emissions resulting from the implementation of the Project will take place in the case of using tripod foundations.

The estimated Zn emission relating to the Project, amounting in the worst case scenario (without additional coating) to approx. 9.79 Mg/year is negligible in relation to the load of this element penetrating annually into the waters of the Baltic Sea with the rivers. In 2006, a total of 3,157.3 Mg of Zn was discharged to the Baltic Sea with water, of which 256.65 Mg originated from Poland (HELCOM, 2011). The expected Zn emission in the worst case scenario is therefore only approx. 0.3% of this load.

The use of Zn-based anodes for the needs of the Project would increase the total annual emission from anticorrosive protection due to their lower current capacity compared to Al-based anodes, and consequently the need to use a larger amount of anodic material. For this type of anodes, 99% of emissions are Zn emissions. Although Zn anodes are technically suitable for offshore wind farms, their higher required number causes structural difficulties. Therefore, Zn anodes are currently not used in offshore wind farms in the German exclusive economic zone (Kirchgeorg et al., 2018).

It is worth mentioning that recently information has appeared on the use of metallic coating (Al, 350 pm) applied by thermal spraying in combination with organic coatings for the wind farm in the Baltic Sea as an alternative technique allowing for avoiding the use of anodes and thus reducing metal emissions (Kirchgeorg et al., 2018).

Taking into account the above, I would like to emphasize that in the case the Applicant decides to use cathodic protection for the needs of the Project, it plans to include it in the design of additional protective coatings or other similar solutions aimed at limiting the necessary amount of anodic material, and thus the emission from this protection. Detailed solutions in the said scope shall be determined at the stage of designing the anticorrosive protection of the Project.

In the currently requested option selected for implementation, the total number of foundations and types of foundations on which wind turbines can be installed was limited. In this option, as part of the Project, only monopiles and jacket foundations may be used for the needs of installation of wind turbines. If a galvanic cathodic protection is used, a reduction in the number of foundations of the BIII OWF, as well as the exclusion of tripod foundations (which require potentially the largest number of anodes) from further considerations concerning the foundation of wind turbines, will allow for reducing the total necessary amount of the anode material, and thus the emission to the marine environment.
Therefore, the impact in this respect will remain insignificant.

Environmental Decision	Decision on environmental conditions issued by the Regional Director for Environmental Protection in Gdańsk on July 7, 2016, ref. No. RDOŚ-Gd-WOO.4211.12.2015.KP.22, for the project named "Construction of the Bałtyk III Offshore Wind Farm"
NPS	National Electricity System
OWF BII/ Project	Bałtyk Środkowy III Offshore Wind Farm
MIP	Offshore Transmission Infrastructure
NIS 2015	The most far-reaching scenario from the 2015 Report, which is a set of parameters of the project causing the most far-reaching impacts, and which was the basis for conducting an environmental impact assessment during the proceedings that ended with the issuance of the Environmental Decision.
Report 2015	The Environmental Impact Assessment Report for the purposes of the procedure finalized by the decision of the Regional Directorate for Environmental Protection of July 7, 2016, ref. No.: RDOS-Gd-WOO.4211.12.2015.KP.22 (zpo)
Report/EIA Report	Environmental Impact Assessment Report for the amendment to the decision on environmental conditions issued for the Bałtyk Środkowy III OWF

1. Introduction

The section presents a description regarding the operation stage of the project, which consists in the construction of an offshore wind farm designated as OWF Bałtyk Środkowy III in parameters modified in relation to the variant for which the Environmental Decision was issued[1]. Since this report is prepared for the purposes of the proceedings to amend the Environmental Decision, thus the Environmental Impact Report[2] - Report 2015, which was the basis for the issuance of the Environmental Decision, is the reference point both for comparing alternatives and for the basis for conducting the environmental impact assessment. Changes in the description of the project are primarily related to the refinement of the approved variant, resulting from technological advances, the progress of design work, including the development of a preliminary plan for the farm and the selection of foundation technology. The presented changes - modifications to the parameters of the BIII OWF approved by the Environmental Decision are the subject of both the description of the project and the basis for conducting an impact assessment.

The above changes did not alter the operation of the project. The description of the operation stage was prepared on the basis of the Environmental Impact Assessment Report Volume III, Section 5 Operation Process, SMDI Doradztwo Inwestycyjne Sp. z o.o. April 2015, and the changes introduced in the currently discussed Contractor's preferred option were taken into account.

The expected life of the investment is about 25 to 30 years. At this stage, it is anticipated that the IMF will require permanent maintenance.

2. The main characteristics of the processes production

Wind power plants will convert the kinetic energy of the wind into electricity as a result of the manufacturing process. The operation of a wind turbine unit is based on a process in which a stream of air creates a buoyant (lifting) force on the aerodynamically formed rotor blades and sets the rotor in rotary motion. The rotating rotor drives a generator that converts the rotor's mechanical energy into low-voltage electricity. The turbine of the wind turbine generates electricity with a voltage of about 400 - 710 volts, which is increased to medium voltage (MV) by the power plant's transformer. The generated electricity is transmitted via submarine MV cable lines to an internal substation. Here the transmitted energy is transformed to the high (HV) or highest (LV) voltage level for transmission to the National Electricity System (NES).

Electricity generation by a wind farm does not require the use of any raw materials or fuels. As a result, air pollutants released during the combustion of such media in conventional power plants are not generated. During the operation of wind turbines, only in situations of windless weather is there a small demand for electricity.

[2] Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

3. Command and control system farms

The BIII offshore wind farm will be controlled by a SCADA (Supervisory Control and Data Acquisition) system, supplied by the turbine manufacturer and overseeing the production process at the farm. The SCADA system collects actual data (measurements), prepares their visualization, controls the production process, reports, as well as alerts (e.g., it can report the need for scheduled or unscheduled equipment maintenance or inspection, or even shut down a damaged power plant automatically) and archives the data. Meteorological monitoring will also be carried out, providing data on sea state and windiness to help plan maintenance work on the farm's equipment, as well as verify wind turbine performance and forecast production. SCADA can also be applied in the transmission of data from ornithological monitoring, if such will be carried out by devices installed on the farm facilities (e.g. radars or cameras). The control systems located at the individual farm facilities will be connected via fiber optic cables (which are part of submarine cables) and, in addition, by radio to a monitoring and control center probably located at the internal substation. The substation, in turn, will be connected to the mainland via cables belonging to the Maritime Transmission Infrastructure (MIP), which is a separate project.

During the life of the farm, systematic, periodic inspections of individual farm components will be carried out in accordance with the Maintenance Plan specified in the contract with the turbine manufacturer. Planned (preventive) and unplanned (corrective) maintenance of the farm will be carried out. In the first years of the farm's operation, this will be a warranty service provided by the equipment manufacturer.

Depending on the cost-benefit analysis, day-to-day farm maintenance activities can be carried out from land (the distance of the chosen port from the farm is a decisive factor), but during periods of intensive work, offshore accommodation of maintenance crews is often used. These can be smaller vessels dedicated to wind farm work, with accommodation for 30 to 100 people, or larger hotel ships. With the planned size of the OWF and the fact that it is being designed within 50 Mm of several seaports, or about 2 hours of transit, it is more likely that most of the work will be carried out from land, using ships and helicopters. Accommodations for maintenance crews can also be made at substations.

It should be added that in connection with the development of offshore wind power, concepts are emerging for the creation of offshore farm management centers, most often placed on a permanent foundation or on specially adapted jack - up platforms, equipped with a helipad, access areas for work boats and ships, and equipped with accommodation for crews and control systems rooms. Thus, it cannot be ruled out that such a solution will be applied in the case of IMF BIII.

An example is the Danish wind farm Horns Rev 2, owned by Ørsted. It is located more than a 2-hour voyage from the coast, while ongoing turbine maintenance work continues throughout the year. As a result, a decision was made to build a residential platform. The platform weighs 422 tons, is three stories high and has 750$^{\text{square meters of}}$ space. It can accommodate 24 employees at a time.

The impacts associated with the construction and decommissioning of the residential platform are similar to those of substations. On the other hand, issues related to the production of domestic sewage and municipal waste will be resolved in accordance with the regulations of international conventions, in the case of the Baltic Sea it is the MARPOL Convention.

Photo 1. Residential platform built for Horns Rev 2 farm (Denmark)

Source: www.orested.com available 03/2022.

4. Ports exploitation

A preliminary analysis of available ports where a farm management center could be located was made. The operating port should be suitable for short-term maintenance and rapid response work.

The operating port should meet a number of requirements, as indicated in the table below.

Table 1. Requirements for the operating port

General requirements	
Transport time to / from the farm or distance	< 2 h or < 50 Mm
Wharf length	80 m
Minimum depth	4 m
Minimum bearing capacity of the soil	5 Mg /^{m2}
Office space, canteen, etc.	approx. 500^{m2}
Accommodation for staff, locker rooms, parking, etc. (social facilities)	for about 15 - 20 people
Availability for service vessels, crew transport vessels, medium-sized jack - up vessels	+

Harbour basin suitable for ships 55 m long and 32 m wide	+
Fuel storage	+
Workshop facilities	+
Helicopter landing pad	+

source: provided by the Contracting Authority

Guided by the above criteria, the technical advisor identified 6 potential operating ports for the BIII offshore wind farm. These are shown in the table below, with the technical advisor stipulating that the ports of Ustka and Darlowo have entrances that are too narrow (both about 40 meters each) to accommodate all vessels used for operations (this is especially true for medium-sized jack - up vessels/barges). However, these ports can be used for personnel transport and emergency response. It cannot be ruled out that by the time the BIII OWF begins operation, there will be changes, e.g. port conversions, changes in technology, which will enable full use of the Ustka and Darłowo ports at the stage of the farm's operation. It cannot be ruled out that other ports, such as Leba, will also be available.

Table 2. Possible operating ports

Port name	Distance from IMF BIII [km]	Depth [m]
Ustka	54	4.5
Darlowo	85	< 5,5
Wladyslawowo	75	4
Kolobrzeg	145	5 - 6
Gdansk	140	15
Gdynia	140	13

source: provided by the Contracting Authority

Possible service ports are marked in dark blue on the map below.

4.1. Anticipated types and traffic vessels

It is expected that for the operation of the BIII offshore wind farm, the vessels described below will be used.

The following are approximations, based on past experience, to illustrate the possible scale of the venture. The final assumptions on ship traffic for the BIII OWF will be made at a later stage, when the construction project is developed and the final concept of organization during the construction phase is worked out. At the same time, it should be emphasized that reducing the number of service units and minimizing their time at sea is one of the main courses of action to reduce the cost of servicing offshore wind farms. Less fail-safe power plants are being built, adapted to marine conditions, and faster and more efficient service units are being developed. Thus, the possibility of a reduction in the figures given below should be expected, not an increase. This includes potential cumulative impacts - operators of other offshore wind farms will very likely use the same or similar state-of-the-art technical solutions offered on the market.

Table 3. Use of ships for substation inspections

Type of ship	Working time	Engine power	Fuel consumption
Auxiliary vessel (support vessel)	6 - 10 inspections per year of each station	1.4 MW	0.17 - 0.35$^{m3/h}$

source: provided by the Contracting Authority

Table 4. Use of cable inspection vessels

Type of ship	Working time	Engine power	Fuel consumption
Small research vessel (small surveying vessel)	1 cable inspection per year, at a speed of 1 km/h	1 MW	0.1 - 0.25$^{m3/h}$

source: provided by the Contracting Authority

Table 5. Use of ships to inspect power plants

Type of ship	Working time	Engine power	Fuel consumption
Auxiliary vessel (support vessel)	2 inspections per year of each turbine, an average of 4 turbines per day + inspections of the entire farm	1.4 MW	0.17 - 0.35$^{m3/h}$

source: provided by the Contracting Authority

Some tasks, especially those related to transporting service teams and equipment, can also be performed by helicopters.

5. Facilities service farms

5.1. Service turbines

During the inspection, ongoing repairs and maintenance will be performed, including replacement of lubricants and hydraulic oils. Based on the results of the inspection, further maintenance work will also be planned. Turbine service vessels will primarily be used to service the turbines. Helicopters may also

be used. If the need for major repairs, such as replacing wings, is identified, it may be necessary to mobilize appropriate equipment, such as ships or jack - up barges.

5.2. Service foundations

The foundations and their equipment will most often be inspected at the same time as the turbines, reducing costs. Ongoing repairs and maintenance will be performed during the inspection. Based on the results of the inspection, further maintenance work will also be planned. Ships will be used to service the foundations, as well as ROVs and divers.

5.3. Substation service power station

The purpose of the inspection will be, in particular, to check the circuits, transformer oil, safeguards. Ongoing repairs and maintenance will be performed during the inspection. Based on the results of the inspection, further maintenance work will also be planned. Ships will be used to service the substation, as well as helicopters. If the need for major repairs, such as replacing transformers, is identified, it may be necessary to mobilize appropriate equipment, such as ships or jack - up barges.

Hazardous substances will be used at substations. The expected types and quantities of these substances are indicated in the table below.

Table 6. Anticipated types and quantities of hazardous substances used in substations

Type of substance	Anticipated quantity
Cooling oil (transformers, chokes)	25 - 40 Mg per 1 transformer 50 - 80 Mg per 1 station of 200 - 300 MW (containing 2 transformers)
Sulfur hexafluoride SF6 (switchgear insulation)	100 - 200 kg per 1 switchboard. Each AC substation will have 2 switchboards (MV and HV)
Diesel (emergency diesel generator)	30^{m3} tank at each station (enough fuel for 5 days of emergency operation)
Refrigerants (AC system cooling)	not specified

source: provided by the Contracting Authority

5.4. Service cables

The purpose of the inspection will be to check the buried condition of the cables and identify any damage to them. Ongoing repairs and maintenance will be performed during the inspection. Based on the results of the inspection, further maintenance work will also be planned. Small research vessels will be used to service the cables, as well as ROVs and divers. If a cable is found to be damaged or uncovered, it may be necessary to use specialized equipment, such as a ship-cable carrier.

6. Zones security

Safety zones are likely to be set up around power plants and substations, with limited access by vessels not owned by the farm operator. The establishment of such a zone is aimed at reducing the risk of their collision with the farm's facilities and, consequently, the risk of danger to human health and life, environmental pollution (including hazardous substances) and serious property damage. The extent of any safety zones and the rules of movement in these zones will be determined at a later stage of the project. So far, the position of the Maritime Office in Slupsk, the authority competent to determine safety zones for the BIII offshore wind farm project, expressed during the consultations conducted for the BSIII and BSII offshore wind farm projects, indicated the legitimacy of creating safety zones with a width of 100 m around the turbines and other elements of the structure at the stage of operation. During construction, the bodies of water where work will be carried out will be gradually, temporarily closed to navigation and fishing. Sailing between power plants may be allowed for vessels up to 45 m in overall length, with a visibility of at least 3 nautical miles[3]. The Maritime Spatial Plan recommends for the 45E basin, where the BIII OWF will be located, the establishment of safety zones with a width of 100 meters around each operating turbine. [4]

7. Obstacle markings and systems warning

The wind turbines, substation and possibly other farm facilities will be properly painted, illuminated and equipped with warning systems as required by Polish aviation and maritime regulations.

In accordance with Article 871 (1) (2) of the Law of July 3, 2002. Aviation Law (i.e: OJ. U. of 2020, item 1970, as amended) construction objects that pose a threat to the safety of aircraft traffic ("aviation obstructions"), should be immediately notified pursuant to Article 871, paragraph 6. To the President of the Civil Aviation Authority (ULC). The form of notification and the method of obstruction marking are specified in the Law of December 14, 2018, Dz. U. 2019 item 235 on Amendments to the Law - Aviation Law and Certain Other Laws, the definition of the procedure for notification and marking of aviation obstacles has been transferred from the regulation to the text of the law. According to the Aviation Law, obstruction markings are understood to be luminous (day or night) and graphic and color markings. The markings should be visible from all sides and should indicate the location, general shape and size of the aerial obstacle. The method of marking the elements of the farm will be determined at the stage of development of the construction project, taking into account the requirements of the applicable regulations.

8. Emissions at the stage of operation

The operation of the BIII offshore wind farm is expected to last about 25 to 30 years. The emissions described in this chapter will therefore occur continuously or periodically during this time. The data

[4] Ordinance of the Council of Ministers of April 14, 2021 on the adoption of a spatial development plan for internal marine waters, territorial sea and exclusive economic zone at a scale of 1:200,000. OJ. U. of 2021, item 935.

presented in this chapter are based on analyses conducted in the 2015 Report for the most far-reaching scenario, which assumes the construction of 200 power plants, with the variant finally approved in the Environmental Decision reducing this number to 120. In the variant that is the subject of this Report, a maximum of 60 wind turbines will be built, which is about 70% less than envisaged in the case of the Project's statement of parameters representing the most far-reaching scenario - NIS 2015, and twice less than specified in the Environmental Decision, and the use of gravity foundations under the turbines has been excluded, which is associated with correspondingly lower emissions during the operation stage. Thus, it is considered that the project will cause lesser impacts from both the most far-reaching scenario - NIS 2015 and the variant approved in the Environmental Decision.

8.1. The work of the farm management center on land

It is envisioned that the farm management center will be located in the service port area and will use its infrastructure, including buildings, parking lots, etc.

Table 7. Emissions related to operation of onshore farm management center

Emissions related to operation of onshore farm management center	
Potential emissions and environmental disturbances	• atmospheric emissions • water intake • wastewater generation • waste generation
Sources of emissions	Operation of the land-based management center
Scale of emissions	Local
Frequency of emissions	Constant (over the lifetime)
Issue duration	During the life of the farm

Environmental Decision	Decision on environmental conditions issued by the Regional Director for Environmental Protection in Gdańsk on July 7, 2016, ref. No. RDOŚ-Gd-WOO.4211.12.2015.KP.22, for the project named "Construction of the Bałtyk III Offshore Wind Farm"
OWF BIII/ Project	Bałtyk Środkowy III Offshore Wind Farm
NIS 2015	The most far-reaching scenario from the 2015 Report, which is a set of parameters of the project causing the most far-reaching impacts, and which was the basis for conducting an environmental impact assessment during the proceedings that ended with the issuance of the Environmental Decision.
PSZW	Permit for erection and use of artificial islands, structures and devices in the Polish maritime areas
Report 2015	The Environmental Impact Assessment Report for the purposes of the procedure finalized by the decision of the Regional Directorate for Environmental Protection of July 7, 2016, ref. No.: RDOS-Gd-WOO.4211.12.2015.KP.22 (zpo)
RDEP	Regional Director of Environmental Protection in Gdansk

1. Introduction

The section presents the decommissioning stage of the project, which consists in the construction of an offshore wind farm designated as OWF Baltic Central III in parameters modified from the variant for which the Environmental Decision was issued[1]. Since this report is prepared for the purposes of the proceedings to amend the Environmental Decision, thus the Environmental Impact Report[2] - Report 2015, which was the basis for the issuance of the Environmental Decision, is the reference point both for comparing alternatives and for the basis for conducting the environmental impact assessment. The changes in the project description are primarily related to the refinement of the approved variant, resulting from the progress of design work, including the development of a preliminary farm layout plan and the selection of foundation technology. The presented changes - modifications to the parameters of the BIII OWF approved by the Environmental Decision are the subject of both the description of the project and the basis for conducting an impact assessment.

The description of the decommissioning process was prepared on the basis of the Environmental Impact Assessment Report Volume II, Section 6 Decommissioning Phase, SMDI Doradztwo Inwestycyjne Sp. z o.o., April 2015. The option planned for implementation did not affect the decommissioning process of the OWF or its selected elements. The changes made to the project description are primarily related to the refinement of the variant selected for implementation, resulting from the progress of design work, including the development of a preliminary plan for the farm and the selection of foundation technology.

2. Description of the liquidation process IMF

The expected life of the investment is about 25 to 30 years. After that time, it may be liquidated (e.g., as a result of technological advances that will make other energy sources applicable). More likely, however, is a scenario in which the decommissioned turbines will be replaced by newer-generation equipment, allowing for greater energy production.

Possible scenarios include dismantling still-operational wind power plants and reselling them for further use, while new plants, with greater capacity, will be installed in their place. This is now a fairly common practice in the onshore wind industry. Used wind turbines from countries where the industry developed earlier than in Poland are now often imported and used in our country. Due to the very rapid development of wind technology, it is expected that this practice will continue.

2.1. Ports possible to use at the stage of decommissioning

Depending on the dimensions of the decommissioned elements, construction and installation or service ports, as described in Sections 4 and 5 of Volume III, may be used to handle the decommissioning of individual farm facilities.

[1] Decision of the Regional Director of Environmental Protection in Gdansk RDOŚ-Gd-WOO.4211.12.2015.KP.22z dated July 72016.

[2] Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

2.2. Reasons decommissioning

Decommissioning of the BIII offshore wind farm (or its individual components, e.g., individual turbines) may occur for the following reasons:

- scheduled decommissioning, due to the depletion of equipment and the end of the farm's operation,
- decommissioning for technical reasons, such as mistakes made during construction, as a result of which the relevant authority will issue an order to demolish the farm equipment,
- liquidation for formal and legal reasons (e.g., due to the expiration of the location decision - PSZW).

Today, the expected life cycle of a wind power plant is a minimum of 20 years, but technological progress in the field of offshore wind energy is very fast, and it is very likely that this time will extend in the case of the BIII OWF to 25-30 years. It is also possible that the farm's equipment will be replaced with new, higher-capacity equipment after a certain period of operation (known as repowering). It should be noted that such an operation will require a new environmental decision and this report does not cover it.

2.3. The basic principles of the process decommissioning

The various components of the wind farm will be decommissioned as follows:

- power plants - removed in their entirety,
- foundations - removed to a depth of 3 m below the level of the seabed or in their entirety, or left,
- internal cables - removed or left in the seabed, covered by sediment,
- protection against leaching - left,
- power substations - removed or left for future use.

It is also possible to decide to leave the foundations intact, so that the artificial reef that will emerge once these structures are populated by benthic organisms will not be destroyed. Such a decision should be one taken immediately before the possible decommissioning of the investment, in consultation with the Regional Director of Environmental Protection in Gdansk and after the completion of a nature inventory.

2.3.1. Decommissioning power plants

Decommissioning a power plant is roughly the reverse process of installing it. The sequence of work is as follows:

1) mobilization of the ship - crane, pontoon / barge with tugboat, service vessels,
2) attaching the crane hooks to the EW, using the same hooks as for installation,
3) cutting the connections between the EW and the connector or foundation,

4) cutting the cables between the EW and the foundation,
5) eW lift from the foundation,
6) placing EW on the pontoon and attaching,
7) land transportation,
8) disposal or sale.

2.3.2. Decommissioning of substations power stations

Offshore substations can continue to be used after the farm is decommissioned. It is possible to connect other IMFs to them. In the case of decommissioning a substation, the sequence of work will be as follows:

1) mobilization of the ship - crane, pontoon / barge with tugboat, service vessels,
2) disconnecting all electrical systems, cutting cables, fixing or removing any station components that are not permanently fixed,
3) possible construction of temporary supports around the legs of the station,
4) attaching the crane hooks to the EW, using the same hooks as for installation,
5) cutting off the legs of the substation just above the foundation and possibly setting the substation on temporary supports,
6) raising the station from its foundation,
7) placing the station on the pontoon / barge and attaching,
8) land transportation,
9) disposal or sale.

2.3.3. Liquidation foundations

The method of eliminating foundations depends on their type.

Monopiles

In the case of monopile decommissioning, the sequence of work will be as follows:

1) mobilization of the ship - crane, pontoon / barge with tugboat, service vessels,
2) attaching the crane hook to the monopile foundation connector,
3) cutting the cables just before they enter the J-tubes,
4) removal of bottom sediments to the depth of the cut (probably about 3 m),
5) cutting the monopile at a depth of about 3 meters below the surface of the seafloor,

6) raising the monopal,
7) laying the monopile on the pontoon and attaching,
8) land transportation,
9) disposal or sale.

It may be necessary to cut the monopal into two or more pieces before transporting it to land.

Tripod or jacket

In the case of the elimination of tripod or jacket foundations, the sequence of work will be as follows:

1) mobilization of the ship - crane, pontoon / barge with tugboat, service vessels,
2) attaching the crane hook to the foundation,
3) cutting the cables just before they enter the J-tubes,
4) partial removal of bottom sediments around the foundation to allow access to the piles,
5) pile cutting,
6) raising the foundation,
7) laying the foundation on the pontoon and attaching,
8) land transportation,
9) disposal or sale.

Foundations gravity

The decommissioning of gravity foundations is a complicated procedure. Two methods are used - partial decommissioning on site or transport ashore in its entirety. Depending on the type of foundation, it can be placed on a barge or floated. In the case of transporting foundations to land, the sequence of work will be as follows:

1) mobilization of the ship - crane, pontoon / barge with tugboat, service vessels,
2) attaching the crane hooks to the foundation,
3) removal of ballast from the foundation,
4) cutting the cables just before they enter the J-tubes,
5) raise the foundation (it may be necessary to partially dig up the foundation),
6) removing the rest of the ballast and water, so as to restore the buoyancy of the foundation,
7) laying the foundation on the pontoon and fastening (in the case of non-floating structures),

8) land transportation,

9) disposal or sale.

2.3.4. Decommissioning cables

The method of cable decommissioning depends on how the cables are laid. In the event that they have been shallowly buried in the sand, then they can be pulled out after digging them up. This may cause uplift of bottom sediments, but this impact is not expected to be significant. If the cables have been laid deeper, then they will most likely be left in place, as decommissioning them would be economically unjustifiable, in addition to having a greater environmental impact.

In the case of cable decommissioning, the sequence of work is as follows:

1) mobilization of a vessel-cable carrier equipped with an ROV,

2) disconnecting the electrical voltage and disconnecting the cables from the foundations,

3) pulling cables to the surface of the seabed using an ROV,

4) pulling the cables through the cable carrier, pulling them aboard and winding them onto a drum,

5) land transportation,

6) disposal or sale.

2.3.5. Survey of the seabed after decommissioning farm

Once decommissioning work is completed, a seabed inspection is required to ensure that all farm components have been removed as required.

2.4. Anticipated types and traffic vessels

During the decommissioning stage of the farm, similar vessels will be used as during the construction stage, as described in Section 4 of this Volume.

Only approximations are given, based on past experience, to illustrate the possible scale of the project. Final assumptions on vessel traffic for the BIII OWF will be made at a later stage, when the construction project is developed and the final concept of organization at the decommissioning stage is worked out. At the same time, it should be emphasized that reducing the number of construction and maintenance units and minimizing their time at sea is one of the main courses of action to reduce costs in offshore wind energy. Today, the market for decommissioning services for offshore wind farms does not exist, so it is difficult to determine the principles, number and efficiency of using vessels in this process. It is to be expected that vessels specializing in OWF construction will be used for this purpose, which in 30-40 years' time, when the BIII OWF is decommissioned, will allow for a reduction in the volumes listed below, rather than an increase.

2.5. Emissions at liquidation stage IMF

The data presented in this chapter are based on analyses conducted in the 2015 Report for the most far-reaching scenario, which assumes the construction of 200 power plants, with the option finally approved in the environmental decision reducing this number to 120. The variant that is the subject of this Report will build about 70% fewer wind turbines than envisioned in the 2015 NIS, and twice as many as specified in the Environmental Decision, and the use of gravity foundations under the turbines has been ruled out. It is therefore considered that the project will result in lower impacts and emissions from both the 2015 NIS and the variant approved by the Environmental Decision.

2.5.1. Movement of service and transport units from the port to the site investment

Table 1. Emissions associated with the movement of service and transport units from the port to the project site

Emissions associated with the movement of service and transport units from the port to the project site	
Potential emissions and environmental disturbances	• noise emissions • atmospheric emissions • wastewater generation • waste generation
Sources of emissions	Ships and helicopters in use during decommissioning
Scale of emissions	Local (industrial port area, transport route, project decommissioning site)
Frequency of emissions	Repeatable (during the period of liquidation)
Issue duration	During the liquidation period
Reversibility of emissions	Reversible
Probability of occurrence	Very large
Preventive, minimizing or mitigating actions	They are described in the following section of the report, which includes an environmental impact assessment
Additional comments	No

Frequency of emissions	Repeatable (during the period of liquidation)
Issue duration	During the liquidation period
Reversibility of emissions	Reversible
Probability of occurrence	Very large
Preventive, minimizing or mitigating actions	They are described in the following section of the report, which includes an environmental impact assessment

Emissions associated with the transportation of dismantled farm components and subassemblies to land	
Additional comments	No

Source: provided by the Contracting Authority

2.5.7. Transport, recovery or disposal of waste from decommissioning of the farm and waste and wastewater from vessels

Table 7. Emissions related to transportation, recovery or disposal of waste from the decommissioning of the farm and waste and wastewater from vessels

Emissions related to transportation, recovery or disposal of waste from the decommissioning of the farm and waste and wastewater from vessels	
Potential emissions and environmental disturbances	Potential irregularities related to transport, recovery or disposal of waste and wastewater
Sources of emissions	Vessels used during construction, vehicles used to transport waste, recovery or disposal sites
Scale of emissions	Local
Frequency of emissions	Repeatable (during the period of liquidation)
Issue duration	During the liquidation period
Reversibility of emissions	Reversible
Probability of occurrence	Very large
Preventive, minimizing or mitigating actions	They are described in the following section of the report, which includes an environmental impact assessment
Additional comments	No

Source: provided by the Contracting Authority

2.5.8. Unplanned emissions related to accidents and accidents

Unplanned emissions related to accidents and accidents during the decommissioning phase are expected to be similar in nature to similar events during the construction phase, as described in Section 4 of Volume II. Therefore, there is no need to describe them again here.

2.5.9. Projected air emissions air

Vessel traffic (at each stage of the project) will involve emissions of pollutants into the air, with average levels:

- NOx: 20-50 kg /$^{m3\ of}$ fuel,
- PM10: 1-2.6 kg /$^{m3\ of}$ fuel,
- $_{SO2}$: 1.7-17 kg /$^{m3\ of}$ fuel.

Environmental Decision	Decision on environmental conditions issued by the Regional Director for Environmental Protection in Gdańsk on July 7, 2016, ref. No. RDOŚ-Gd-WOO.4211.12.2015.KP.22, for the project named “Construction of the Bałtyk III Offshore Wind Farm”
EW	Wind power plants
OWF BIII / Project	Bałtyk Środkowy III Offshore Wind Farm
MSE	Offshore substation
NIS 2015	The most far-reaching scenario from the 2015 Report, which is a set of parameters of the project causing the most far-reaching impacts, and which was the basis for conducting an environmental impact assessment during the proceedings that ended with the issuance of the Environmental Decision.
Report 2015	The Environmental Impact Assessment Report for the purposes of the procedure finalized by the decision of the Regional Directorate for Environmental Protection of July 7, 2016, ref. No.: RDOS-Gd-WOO.4211.12.2015.KP.22 (zpo)
Report/EIA Report	Environmental Impact Assessment Report for the amendment to the decision on environmental conditions issued for the Bałtyk Środkowy III OWF
RDEP	Regional Director of Environmental Protection in Gdansk
EIA Act	Act of October 3, 2008 on access to information on the environment and its protection, public participation in environmental protection and on environmental impact assessments(consolidated text, Journal of Laws of 2022, item 1029).
WA2015	Alternative option from the 2015 Report assuming 200 wind turbines
WR2015	The implementation variant from the 2015 Report assuming the implementation of 120 wind power plants, for which a decision on environmental conditions was issued by the Regional Director of Environmental Protection in Gdansk on July 7, 2016 (sign: RDOS-GdWOO.4211.12.2015.KP.22) for the project titled "Wind power plant. "Construction of the Polenergia Baltic Central III offshore wind farm"
WR60	Option selected for implementation

1. Introduction

Below is information summarizing the most important emissions that an offshore wind farm may cause at various stages of construction, operation and decommissioning. Each type of emission has been assigned a source, i.e. an IMF component or activity in the operation of the farm that causes the emission. Then, for each emission, the type of impacts it causes in the marine ecosystem is indicated, while indicating the receptor/recipient of the impact, both direct and indirect.

Then, the factors, on the side of the environment and the Project, which influence the occurrence and scale of the impact were determined for each impact, and the most far-reaching scenario for the BIII OWF presented in the 2015 Report was indicated, i.e. such a technical solution, which in all variants considered at that time (the implementation variant assuming the implementation of 120 wind power plants, for which the Environmental Decision was issued - WR2015, and the alternative variant assuming the implementation of 200 wind power plants - WA2015 would cause the impact of the greatest scale - NIS 2015. Finally, the 2015 NIS was compared to the current variant selected for implementation-WR60, in the parameters that could cause its most far-reaching impacts.

Since the environmental assessment conducted in the 2015 Report was based on the parameters set by the 2015 NIS, these parameters are therefore the appropriate benchmark for conducting analyses related to changes in the nature or magnitude of impacts associated with the proposed modifications to the Project. At the same time, it should be emphasized that due to the fact that for the most part the parameters of the Project proposed for modification have not been increased, and most of them are significantly reduced, the consequence will be a reduction in the magnitude of impacts for most types of emissions or disturbances. The exceptions are the parameters related to the maximum overall height of the power plant (which increased by 97.5 meters compared to WR2015) and the maximum rotor diameter (which increased by 57.5 meters compared to WR2015). The change in parameters in this regard is offset many times over by reducing the number of power plants by about 70% compared to WA2015 and 50% compared to WR2015, respectively. In addition to a 50% reduction in the number of power plants in the currently proposed implementation variant, it was decided to limit the types of foundations considered that will be used for wind power plants. The developer has decided to rezegn from the possibility of using gravity foundations for wind turbines. This will reduce the area of the bottom occupied by foundations in WA2015 compared to the currently preferred implementation option by 97.4%. The investor also decided to reduce the diameter of the monopile foundations from 12.5m to 10.0m in the current implementation variant.

Nevertheless, the types of emissions and disturbances themselves, their sources and receptors will remain unchanged, thus the matrix compiled for the 2015 Report remains valid. However, the juxtaposition of the 2015 NIS with the proposed post-modification parameters of the Project in the linkage matrix makes it possible, in one place, to briefly illustrate the nature and direction of the proposed modifications to the Project in the minor environmental decision amendment proceedings.

The matrix of linkages, between emissions, impacts and parameters of the project, constructed in this way, served at subsequent stages to assess the impact of individual solutions, processes and technologies on the marine ecosystem, which is presented in the following chapters of Volume IV.

2. A matrix of linkages between emissions and impacts IMF

Table 1. A matrix of interrelationships of potential emissions and disturbances caused by the OWF and their sources, direct and indirect impacts on the environment and the factors determining them.

Type of emission or disturbance	Source of emissions	Type of impacts	Which elements of the ecosystem are directly affected	Linkages (indirect impacts)	Environmental factors affecting the scale of impact	Parameters of the project affecting the scale of impact	The most far-reaching scenario of the 2015 NIS	Project - variant selected for implementation (Project after update)
Disruption of sediment structure (and any other physical disturbance of the seabed)	• Preparation of the bottom for the foundation • Geotechnical drilling • Installation of foundations • Laying a protective layer against leaching	• Habitat destruction and alteration • Reduction in population size • Reduction of the foraging base • Potential for damage to historic objects at the bottom • Ability to wash out or pick up raw materials while preparing the bottom for foundations • Possibility of backfilling mineral deposits with dredging spoils	• Sediments • Bentos • Fish	• Seabirds • Mammals • Cultural heritage	• Bottom type • Thickness of the sediment layer	• Number of foundations • Type of foundation • Foundation diameter • Width of the protective layer	Construction of 200 gravity foundations of the maximum diameter under consideration, i.e. 40 m	Construction of 60 monopile foundations with a maximum diameter of 10 m or jacket type and implementation of one gravity foundation (with a maximum base diameter of 50 m) for the implementation of MSEs
Increase in the concentration of suspended solids in water	• Preparation of the bottom for the foundation • Installation of foundations • Cable laying	• Change in living conditions • Turbidity of water	• Bentos • Fish • Mammals • Seabirds • Hydrological conditions	• Seabirds • Mammals • Tangible assets	• Type of sediment • Directions of currents • Speed of currents • Sedimentation rate	• Number of foundations • Type of foundation • Foundation diameter • Cable lengths	Construction of 200 gravity foundations of the maximum diameter under consideration, i.e. 40 m	Construction of 60 monopile foundations with a maximum diameter of 10 m or jacket type and implementation of

Type of emission or disturbance	Source of emissions	Type of impacts	Which elements of the ecosystem are directly affected	Linkages (indirect impacts)	Environmental factors affecting the scale of impact	Parameters of the project affecting the scale of impact	The most far-reaching scenario of the 2015 NIS	Project - variant selected for implementation (Project after update)
						• Width of the protective layer		one gravity foundation (with a maximum base diameter of 50 m) for the implementation of MSEs
Release of pollutants and nutrients from the sludge into the water body	• Preparation of the bottom for the foundation • Installation of foundations • Cable laying • Heat emission from cables	• Increase in the amount of pollutants and nutrients in water • Change in living conditions • Decline in population size • Increase in the concentration of contaminants in the bodies of fish from consuming species	• Bentos • Fish • Mammals • Hydrochemical conditions	• Seabirds • Health and life of people	• Type of sediment • Sludge contamination • Speed and direction of currents	• Number of foundations • Type of foundation • Foundation diameter • Cable lengths • Depth of cable burial	Construction of 200 gravity foundations of the maximum diameter under consideration, i.e. 40 m	Construction of 60 monopile foundations with a maximum diameter of 10 m or jacket type and implementation of one gravity foundation (with a maximum base diameter of 50 m) for the implementation of MSEs
Deposition of agitated sediment	• Preparation of the bottom for the foundation • Installation of foundations • Cable laying	• Change in living conditions • Possibility of additional backfilling of mineral deposits	• Bentos • Fish	• Seabirds • Mammals • Cultural heritage • Tangible assets	• Type of sediment • Directions of currents • Speed of currents • Sedimentation rate	• Number of foundations • Type of foundation • Foundation diameter • Cable lengths	Construction of 200 gravity foundations of the maximum diameter under consideration, i.e. 40 m	Construction of 60 monopile foundations with a maximum diameter of 10 m or jacket type and implementation of one gravity foundation (with a maximum base diameter of 50 m) for the implementation of MSEs

Type of emission or disturbance	Source of emissions	Type of impacts	Which elements of the ecosystem are directly affected	Linkages (indirect impacts)	Environmental factors affecting the scale of impact	Parameters of the project affecting the scale of impact	The most far-reaching scenario of the 2015 NIS	Project - variant selected for implementation (Project after update)
The "artificial reef" effect	• Foundations laid	• Creation of new habitats • Changing species compositions • Growth of the food base • Change in living conditions • Increase the quantity and quality of professional and tourist fishing • Increase in revenue from the fishing and tourism industries	• Bentos • Fish	• Seabirds • Fish • Mammals • Tourism and recreation • Fishing • Tangible assets	• Physical and chemical parameters of water	• Number of foundations • Type of foundation • Foundation diameter	Construction of 200 gravity foundations of the maximum diameter under consideration, i.e. 40 m	Construction of 60 monopile foundations with a maximum diameter of 10 m or jacket type and implementation of one gravity foundation (with a maximum base diameter of 50 m) for the implementation of MSEs
Increased underwater noise and vibration	• Foundation placement • Cable laying • Ship traffic • Operation of the power plant • Decommissioning of farm facilities	• Displacement from habitats • Change in living conditions • Injury • Mortality • Reduction in catches	• Fish • Mammals • Seabirds	• Seabirds • Mammals • Fishing	• Background noise level • Depth • Formation of the bottom • Depth structure of the bottom • Wind speed	• Type of foundation • Number of foundations • Foundation diameter • Foundation time for 1 foundation • Effective driving time • Number of impacts when driving the foundation • Hydraulic hammer power • Depth and method of cable laying	Construction of 200 monopile foundations of the maximum diameter under consideration, i.e. 10 m (WA2015) or removal of gravity foundations (200 units, WA2015)	Construction of 60 monopile foundations with a maximum diameter of 10 m or jacket type and the implementation of one gravity foundation (with a maximum base diameter of 50 m) for the implementation of MSE or the decommissioning of monopile or jacket type foundations (60 pieces) and a gravity foundation

Type of emission or disturbance	Source of emissions	Type of impacts	Which elements of the ecosystem are directly affected	Linkages (indirect impacts)	Environmental factors affecting the scale of impact	Parameters of the project affecting the scale of impact	The most far-reaching scenario of the 2015 NIS	Project - variant selected for implementation (Project after update)
						• Number of construction vessels		
Heat emission from cables	• Cables	• Increase in water and sediment temperature • The appearance of alien species	• Water • Sediments	• Abiotic environment • Archaeology and cultural heritage • Bentos • Fish	• Type of sediment • Thermal conditions at the bottom	• Cable lengths • Type of cables • Burial depth	Construction in WA of 200 power plants with cable infrastructure (With the caveat that WR2015, ie. 120 power plants, will likely require the laying of cables of similar length, due to the greater distances between wind turbines	Construction of 60 power plants with cable infrastructure it is assumed that a similar number of cables may be laid as for NIS 2015 due to the distances between EWs)
Emergence of new structures under the sea surface	• Foundations • Cables	• Barrier effect • Change in living conditions • Changes in the regime of sea currents and waves • Difficulties for shipping and navigation • Orders for the maritime industry	• Fish • Mammals • Hydrological conditions • Shipping and navigation • Maritime industry • Tangible assets		• Water transparency • Wind speed	• Number of power plants • Type of foundation • EW density/km2 • Diameter of foundations • Constant noise and vibration • Cable length	Construction of 206 gravity foundations with the maximum diameter under consideration, i.e. 40 m (WA2015)	Construction of 60 monopile foundations with a maximum diameter of 10 m or jacket type and implementation of one gravity foundation (with a maximum base diameter of 50 m) for the implementation of MSEs
Emission of electromagnetic field and radiation	• Cables	• Orientation disorder • Changes in the use of space	• Fish • Mammals • Radar systems			• Cable type • Cable length • Buried depth • Number of MSEs	Construction in WA2015 of 200 power plants with cable infrastructure (with the caveat	Construction of 60 power plants with cable infrastructure it is assumed that a similar number of

Type of emission or disturbance	Source of emissions	Type of impacts	Which elements of the ecosystem are directly affected	Linkages (indirect impacts)	Environmental factors affecting the scale of impact	Parameters of the project affecting the scale of impact	The most far-reaching scenario of the 2015 NIS	Project - variant selected for implementation (Project after update)
		• Interference with radar systems • Disruption of navigation and navigation	• Shipping and navigation			• MSE foundation height	that WR2015, ie. 120 power plants, will likely require laying cables of similar length, due to the greater distances between EWs)	cables may be laid as for NIS 2015 due to the distances between EWs)
Appearance of new structures above sea level	• Rotor • Tower • Electricity substations	• Barrier effect • Displacement from habitats • Collision fatality rate • Landscape changes • Difficulties for shipping and navigation • Orders for the maritime industry • Increase innovation in industry • Growth in employment / wages	• Seabirds • Migratory birds • Landscape • Bats • Shipping and navigation • Maritime industry • Tangible assets			• EW height • Rotor diameter • Number of structures • EW density	Construction of 200 power plants with a minimum clearance of 20 m, a maximum rotor diameter of 200 m and a maximum height of the entire structure of 275 m and 6 MSEs (WA2015)	Construction of 60 power plants with a minimum clearance of 20 m, a maximum rotor diameter of 255 m and a maximum height of the entire structure of 300 m and (the parameter of diameter and total height are not changed from the condition set by the Environmental Decision) and 1 MSE
Increased traffic of vessels and helicopters	• Watercraft (ships, barges) • Helicopters	• Barrier effect • Hounding • Collisions with animals	• Seabirds • Migratory birds • Bats • Marine mammals • Fish • Bentos • Water			• Number of ships • Type of ships	Construction, operation and decommissioning of 200 farm facilities (WA2015)	Construction, operation and decommissioning of 60 farm facilities and 1 MSE

Type of emission or disturbance	Source of emissions	Type of impacts	Which elements of the ecosystem are directly affected	Linkages (indirect impacts)	Environmental factors affecting the scale of impact	Parameters of the project affecting the scale of impact	The most far-reaching scenario of the 2015 NIS	Project - variant selected for implementation (Project after update)
			• Sediments					
Surface noise emissions	• Rotor • Ship traffic	• Hounding • Displacement from habitats • Deterioration of living conditions for people in the area of the farm (e.g., on ships)	• Seabirds • Marine mammals • Fish • Tourism • Health and life of people		• Wind speed • Wind directions • Wave height	• Sound power of the turbine • Tower height • Number of EW • Number and type of ships	Construction / decommissioning in WA2015 of 200 power plants with infrastructure (resulting in the longest noise emissions due to the length of construction or decommissioning; noise levels will be the same regardless of the number of power plants built) Operation in WA2015 of 200 power plants (resulting in noise emissions of the highest level and extent)	Construction / decommissioning in the WR of 60 power plants and 1 MSE with infrastructure (resulting in the longest noise emissions due to the length of construction or decommissioning; noise levels will be the same regardless of the number of power plants built, but the length of emissions depends on the number of power plants) Operation of 60 power plants (resulting in noise emissions of the highest level and extent)
Air pollutant emissions	• Ships • Helicopters	• Deterioration of animal habitat • Deterioration of living conditions for people in the area of the farm (e.g., on ships)	• Air quality • Health and life of people	• Birds • Mammals	• Wind speed • Wind directions	• Number of ships • Engine power • Fuel consumption • Number of working days	Construction / operation / decommissioning in WA2015 of 200 power plants with infrastructure (causing the most air emissions from	Construction / operation / decommissioning of 60 power plants and 1 MSE with infrastructure (causing the most air emissions from ships and helicopters,

Type of emission or disturbance	Source of emissions	Type of impacts	Which elements of the ecosystem are directly affected	Linkages (indirect impacts)	Environmental factors affecting the scale of impact	Parameters of the project affecting the scale of impact	The most far-reaching scenario of the 2015 NIS	Project - variant selected for implementation (Project after update)
							ships and helicopters)	depending on the number of power plants)
Water pollution emissions	• Ships • Protection against corrosion • Grouting • Measures for protection against overgrowth of marine structures	• Deterioration of living conditions	• Hydrochemical conditions • Bentos • Fish • Marine mammals • Seabirds		• Physical and chemical properties of water	• Number of ships • Number of foundations • Type of foundation • Type of binder	Construction / operation / decommissioning in WA2015 of 200 power plants with infrastructure (causing the most air emissions from ships and helicopters)	Construction / operation / decommissioning of 60 power plants and 1 MSE with infrastructure (causing the most air emissions from ships and helicopters, depending on the number of power plants)
Waste generation	• Construction process • Construction and service vessels • Construction and service support					• Number of EW • Number of foundations • Number of ships • Timing of the construction process • Frequency of service	Construction / operation / decommissioning in WA2015 of 200 power plants with infrastructure (causing most waste generation)	Construction / operation / decommissioning in 60 power plants with infrastructure (causing the most waste generation, depending on the number of power plants)
Light phenomena	• Power plants in operation	• Strobe effect • Shadow flicker	• Marine mammals • Seabirds		• Height of the power plant • Current position of the sun relative to the position of the power plant	• Number of power plants • Height of the power plant • Rotor diameter • Number of sunny days	Operation of 200 power plants (WA2015)	Operation of 60 power plants and 1 MSE

Environmental Decision	Decision on environmental conditions issued by the Regional Director for Environmental Protection in Gdańsk on July 7, 2016, ref. No. RDOŚ-Gd-WOO.4211.12.2015.KP.22, for the project named "Construction of the Bałtyk III Offshore Wind Farm"
BIII OWF	Bałtyk Środkowy III Offshore Wind Farm
EIA	Environmental impact assessment
Report/EIA Report	Environmental Impact Assessment Report for the amendment to the decision on environmental conditions issued for the Bałtyk Środkowy III OWF

1. Introduction

The section presents a report on the study of the acoustic environment in the area of OWF BIII near Slupsk Shoal, and which forms the basis for noise analyses. The results of the study were used as the basis for conducting an environmental impact assessment as part of the proceedings that resulted in the Environmental Decision[1].

Since the total area of the farm that is the subject of this report, where the construction of the power plant is possible, is slightly smaller and within the boundaries of the area described in the Environmental Impact Report for the Central Baltic III offshore wind farm, prepared in 2015, the sections of Volume IV of the EIA Report containing the assessment of the impact on individual receptors cite the results of the studies from the report that is Appendix A.

The report on acoustic background monitoring in the area of the offshore wind farm "Baltic Central III" in Polish and English language versions is attached as Appendix A.

IMF BII	Offshore wind farm OWF Bałtyk II (originally: Bałtyk Środkowy II and Polenergia Bałtyk II)
OWF BIII / Project	Bałtyk Środkowy III Offshore Wind Farm
IMF Baltica	Offshore Wind Farm Baltica
NIS 2015	The most far-reaching scenario from the 2015 Report, which is a set of parameters of the project causing the most far-reaching impacts, and which was the basis for conducting an environmental impact assessment during the proceedings that ended with the issuance of the Environmental Decision.
SELcum sound exposure level	Summary of exposure levels to the sound of multiple consecutive beats. Calculated as: SELcum = SEL single + 10 log (N); N = number of beats
Sound pressure level SPLpeak	Expression of the highest sound pressure in decibels (dB)
PTS	Permanent elevation of the hearing threshold as a result of physical damage to the sensory hair cells of the ear.
Report 2015	The Environmental Impact Assessment Report for the purposes of the procedure finalized by the decision of the Regional Directorate for Environmental Protection dated July 7, 2016, ref. No. RDOŚ-Gd-WOO.4211.12.2015.KP.22
Temporary shift of the TTS threshold	Temporary elevation of the hearing threshold due to fatigue of the sensory hair cells of the ear
Hertz (Hz)	A unit of frequency where 1 Hz = 1 cycle per second. One Kilkohertz is 1,000 cycles per second

1. Introduction

Sound can be generated during all stages associated with the construction, operation and decommissioning of an offshore wind farm. The biggest concern, however, is the underwater noise emitted during construction, due to the high sound levels generated when piles are driven into the seabed (piling). Marine life forms such as fish and marine mammals are sensitive to sound, hence noise associated with wind farm construction activities can affect them over long distances. Particularly sensitive are those marine organisms that have developed relatively good hearing , such as whales and seals. The hearing of both these groups of animals is several times more sensitive and covers a much wider range of frequencies than human hearing.

This section summarizes the results of numerical modeling of propagating sound due to generated noise caused by the installation of 10-meter diameter monopile foundations, which is the most far-reaching scenario for the variant selected for implementation, i.e. the proposed modified parameters of the Project approved by the Environmental Decision. The generated sound levels were compared with the recorded background sound spectrum to show changes in the sound field during the construction of the wind farm.

Wind farm construction methods vary for specific projects and thus generate sounds with different characteristics into the marine environment.

Several modeling studies of underwater noise propagation associated with the installation of offshore wind farm foundations have been carried out in the Project area in recent years. The results of these modeling studies were presented in the environmental impact reports for the BII OWF project (previously: WBII, SMDI 2015), the IMF BIII project (formerly: WBIII, SMDI 2015), the Baltic Power OWF project (MEWO S.A, IMUMG, 2020), the FEW Baltic II project (Baltic Trade and Invest Sp. Z o.o., 2019), and the Baltica OWF (IMG/MEWO S.A. 2017).

In all studies, the use of a monopile foundation, driven into the bottom, was assumed as the furthest-reaching scenario, generating the largest sound propagation ranges.

Originally, for the purpose of assessing the Project's environmental impact, both for the variant approved in the Environmental Decision and the farthest-reaching scenario evaluated in the 2015 Report (NIS 2015), it was assumed that the maximum diameter of monopile foundations would be up to 10m, with modeling done for a diameter of 7.5m. Based on the directions of noise propagation determined by modeling for the BSIII offshore wind farm, as well as the maximum ranges for a 7.5-meter diameter monopole, noise impact zones were estimated for marine mammals (seals and porpoises) and fish occurring in the area of the planned farm, where injury, temporary displacement of the hearing threshold and behavioral response of avoidance may occur. Since there is no knowledge of the increase in sound levels during piling for larger piles due to the increase in diameter, it was assumed that a 7.5-meter-diameter monopile (8MW) and a 10-meter-diameter pile (10 MW) emit the same sound levels.[1]

At present, based on the design work carried out so far to clarify the parameters of the Project, a diameter of 10 m monopile foundations has been assumed. Also currently under consideration is the

[1] Environmental Impact Assessment of the offshore wind farm Baltic Central III. Numerical modeling of noise propagation generated by piling. DHI February 2015 (Volume II, Chapter 9 of the 2015 Report)

use of jackhammers with a higher capacity than originally planned for the installation of foundations, which is related to the rapid development of technologies used for the construction of offshore wind farms. In order to verify the impact of the changes in question on the predicted ranges of underwater noise impacts on marine organisms, particularly in relation to the closest Natura 2000 area protecting marine mammals, i.e. the Ostoja Słowińska area (PLH220023), a simulation of underwater noise propagation from the piling of a 10 m diameter monopile foundation using a 4,500 kJ pneumatic hammer was carried out. The location of the foundation in the BIII OWF development area for modeling purposes was selected to be as close as possible to the boundary of the aforementioned Natura 2000 area. The modeling was performed for two scenarios - with and without the use of noise mitigation measures in the form of a single bubble curtain, which allows us to determine the predicted effectiveness of this solution in minimizing underwater noise propagation. It should be noted here that the application of a minimization measure in the form of a bubble curtain or other, with no lesser degree of reduction in the spread of underwater noise, as a mandatory recommendation was included in the conclusions of the 2015 Report, was also indicated as a condition of the Environmental Decision. The simulation was performed taking into account the current literature on the subject, including, among other things, the threshold values for potential hearing damage in marine mammals as defined in the article np. *"Marine Mammal Noise Exposure Criteria: Updated Scientific Recommendations for Residual Hearing Effects"* by Southall et al. published in 2019. It should be mentioned that due to the development of knowledge on the sensitivity of marine organisms to underwater noise impacts that has occurred since 2015. (threshold values of impacts and weighting functions), the results of the modeling in question are not comparable to the results of the modeling performed for the 2015 Report. A summary of the results of the modeling conducted and the predicted ranges of underwater noise impacts in the form of temporal shift of hearing threshold (TTS) in harbor porpoise and sealfish occurring in the Project area without and with the application of a single bubble curtain are presented in Chapter 3 of this section.

2. Methodology

This chapter presents a description of the methods used and the input data used to model sound propagation during monopile driving, conducted in 2020.

The report[2] presenting the results of the modeling, which is the basis for the development of this section of the Report, estimates the intensity of noise generated by 10-meter diameter monopile piling at a hammer impact force of 4,500 kJ.

Sound propagation in the environment was modeled as a function of bathymetry, seafloor conditions, water temperature, salinity and sound speed profile, using the dBSea program.

The modeling used the basic assumptions and settings set forth in the 2015 DHI report[3], but also used information that was not known in 2015, so the results obtained in 2020 are more precise than those in the aforementioned report. In particular, the information includes the latest limits for possible effects on living organisms, as well as higher hammer energy and a different approach to propagation model configuration (Combination of parabolic wave equation and ray-tracer method).

[2] Sound Simulation Pile Driving for Baltic WF, Equinor 2020

[3] Environmental Impact Assessment of the offshore wind farm Baltic Central III. Numerical modeling of noise propagation generated by piling. DHI February 2015 (Volume II, Chapter 9 of the 2015 Report)

Noise from pile driving is transient and intermittent. Acoustic energy is generated when the hammer hits the pile and is transferred to the water. However, this complex process is simplified by describing sound as emitting from a point source.

The strength of sound at the source depends mainly on:

- Size (diameter), shape, length and diameter of the pile
- Hammer size and energy

How this sound propagates in the environment depends mainly on:

- Bathymetry
- Profile of the speed of sound in water (a function of salinity, temperature and depth)
- Type and thickness of sediment
- The type and depth of the rock substrate
- Volume damping (function of viscosity, pressure, salinity, acidity)

In general, higher-frequency sounds are more strongly attenuated than lower-frequency sounds, and in shallow water there is more interaction with the seafloor and water surfaces, which also leads to greater attenuation at a distance.

The dBSea tool (Irwin Carr Consulting) was used to model sound propagation. This tool allows modeling of sound propagation in its full range, taking into account all the parameters mentioned. It also offers several mathematical tools for modeling sound propagation. For frequencies below 400 Hz, a tool using the parabolic wave equation was used. For frequencies above 400 Hz, a ray-tracer tool was used.

The results were calculated along 36 radial slices (10 degrees per slice). Along each slice, sound properties were calculated at a distance of 60 m (2400 points of coverage). The depth resolution was 2 meters. For graphical display, the calculated results were projected / extrapolated onto a grid with a resolution of 60 m. When calculating and displaying the range, the highest values found are projected onto the surface.

The sound sources were entered into the propagation model as point sources at half water depth, i.e. 13m for OWF BIII.

The source strength and frequency content of the sound source were taken from the literature based on theoretical considerations and field measurements.

Sound propagation in the environment was modeled based on the characteristics of a 4500 kJ impact hammer. This is the strongest possible source, and the lower hammer energy will have less impact due to reduced energy and peak pressure at the source. The effect of using a single bubble curtain for a 4500 kJ hammer was also simulated. SELcum24h was calculated assuming 16800 strokes, which corresponds to 4-5h of pile driving per day.

3. Results modeling

The modeling for OWF BIII conducted in 2020 considered 2 variants of noise propagation: without mitigation measures and with the use of a bubble curtain to limit sound propagation in one, which

allows us to determine the predicted effectiveness of this solution in minimizing underwater noise propagation. A summary of the results of the modeling performed is shown in Table 2.

Table 1. The ranges of underwater noise impacts emitted during the piling of a 10 m diameter foundation with a 4,500 kJ jackhammer in the BIII offshore wind farm development area - with and without the use of a single bubble curtain, reducing the sound pressure level (SPL) by 14 dB and the sound exposure level (SEL) by 11 dB.

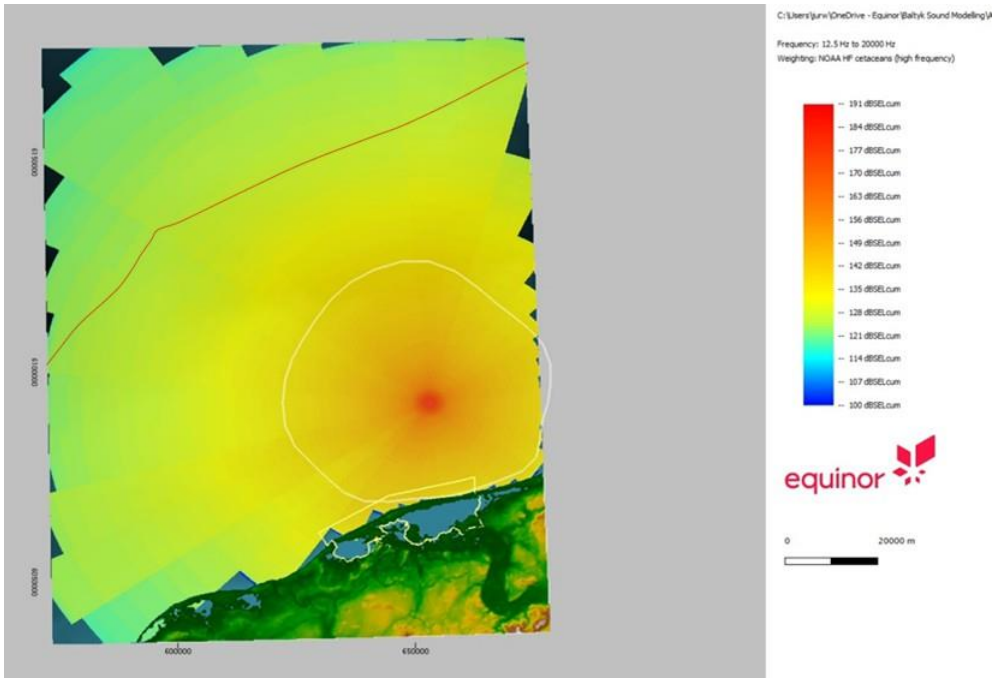
*Threshold values were adopted for the group of fish with the best-developed hearing (fish in which the swim bladder is connected to the hearing organs).

Source: own study based on the results of modeling performed for the BIII OWF project.

In the no-mitigation variant, threshold values for SPLpeak are exceeded less than 1,000 meters from the source. Thus, none of the threshold criteria at the boundary of the Natura 2000 area Ostoja Słowińska was exceeded.

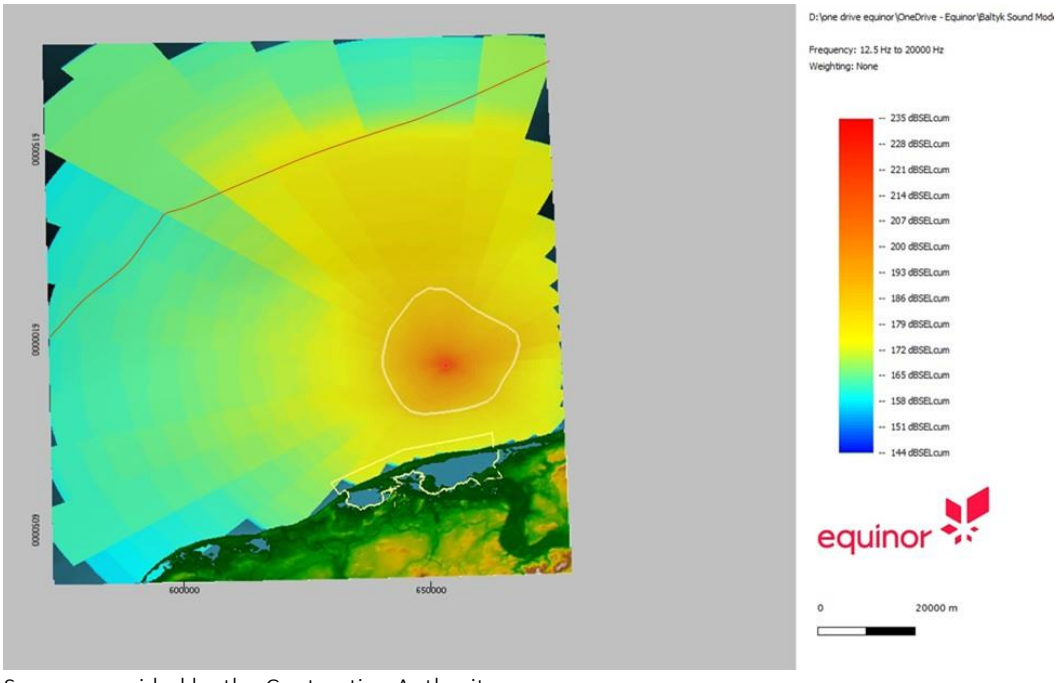
Threshold values for TTS for SELcum24 in very high-frequency cetaceans and pinnipeds were exceeded at the Natura 2000 site boundary, but the threshold level for TTS for fish was not exceeded, as shown in the figures below.

Figure 1 10m diameter monopile, 4500 kJ, SELcum 16800 strokes. The white line indicates a TTS level of 140dB for cetaceans with high sensitivity to very high frequency (VHF) sounds. The yellow line represents the border of the Natura 2000 area Ostoja Słowińska.



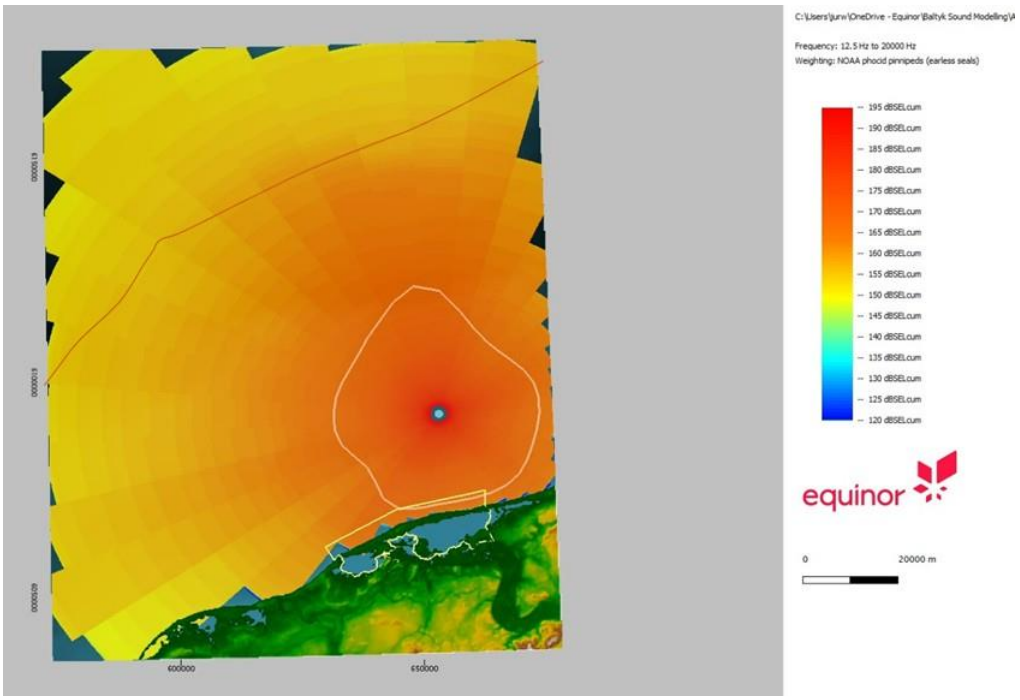
Source: provided by the Contracting Authority

Figure 2 Monopal with a diameter of 10m, 4500 kJ, SELcum 16800 strokes. The white line indicates a TTS level of 186dB for fish. The yellow line represents the border of the Natura 2000 area Ostoja Słowińska.



Source: provided by the Contracting Authority

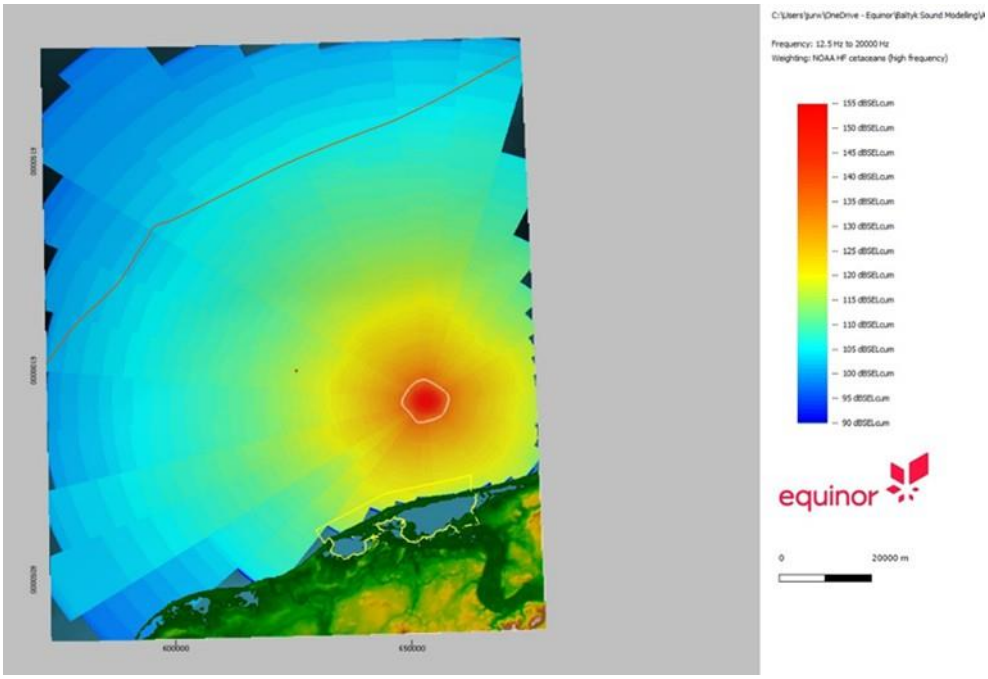
Figure 3 Monopal with 10m diameter, 4500 kJ, SELcum 16800 strokes. The white line indicates the TTS level of 170dB for sealife (PW). The yellow line represents the border of the Natura 2000 area Ostoja Słowińska.



Source: provided by the Contracting Authority

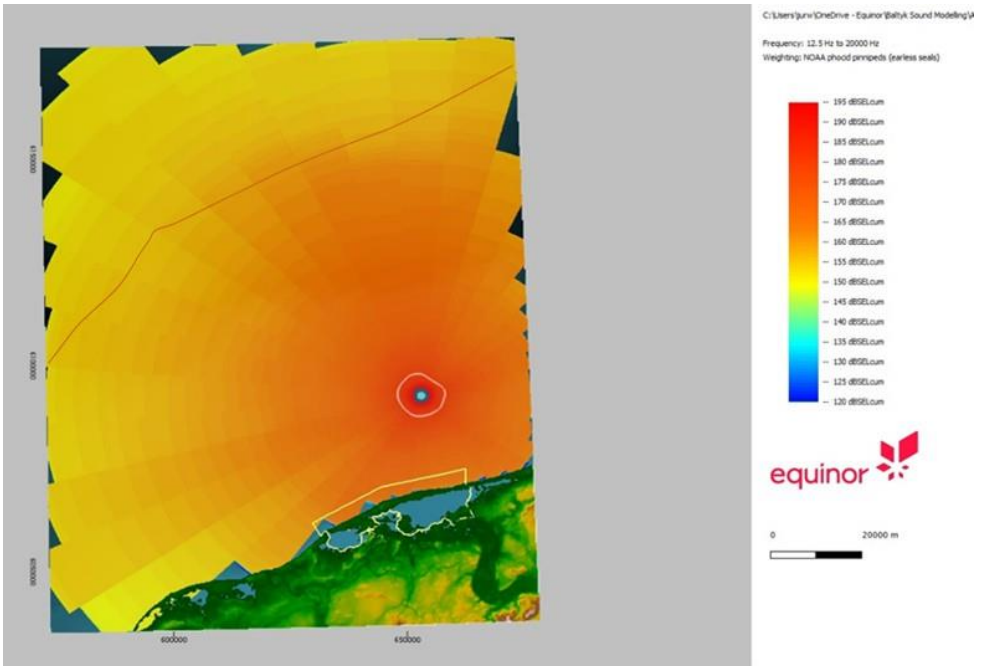
The introduction of a damping effect in the form of a single bubble curtain and a corresponding reduction in SEL and SPL values at the source led to a situation where none of the threshold values were exceeded at the boundary of the Natura 2000 area Słowińska Ostoja (Figure 5, Figure 6).

Figure 4 Monopal 10m diameter, 4500 kJ, mitigated by 11 dB by bubble curtain, SELcum 16800 strokes. The white line indicates a TTS level of 140dB for cetaceans with high sensitivity to very high frequency (VHF) sounds. The yellow line represents the border of the Natura 2000 area Ostoja Słowińska.



Source: provided by the Contracting Authority

Figure 5 Monopal 10m diameter, 4500 kJ, mitigated by 11 dB due to bubble curtain, SELcum 16800 beats. The white line indicates the TTS level of 170dB for sealife (PW). The yellow line represents the border of the Natura 2000 area Ostoja Słowińska.



Source: provided by the Contracting Authority

The modeling exercise also calculated the distances from the sound sources (pile driving) to the point where the acoustic energy (SEL) or sound pressure (SPL) fell below the respective thresholds. Threshold values of impact on porpoises and seals were used for the assessment, and these distances were related to the Natura 2000 area lying south of OWF BIII (where these mammals are protected).

The TTS impact zones with a maximum distance of 34 km from BIII for seals clearly exceeded the distances to the Natura 2000 area. The mitigation effect was modeled with one bubble curtain reducing SEL values by 11dB and SPLpeak values by 14dB. With this mitigation measure, none of the thresholds were exceeded at the boundary of the Natura2000 area Ostoja Słowińska.

It should be borne in mind, of course, that sound propagation modeling is subject to some uncertainty, and determining the extent of the impact to the nearest meter is not indicative of such accuracy and precision of the results. However, the results of the modeling study indicate that, with mitigation measures, none of the threshold values for potential impacts on cetaceans and seals (TTS, PTS) will be exceeded at the boundary of the Natura 2000 site Slovianska Ostoja Słowińska. Model calculations have shown that one bubble curtain is enough to achieve the desired results. A hammer energy of 4500 kJ can also be seen as a worst-case scenario, so additional mitigation can be achieved, using less hammer energy if possible.

However, the results of modeling underwater noise propagation from foundation piling in the BIII offshore wind farm development area with and without the bubble curtain, presented in Table 1 and in the figures, indicate that this solution is highly effective in reducing the extent of noise impacts on marine organisms. It should be noted here that the bubble curtain is one of the feasible methods to reduce underwater noise propagation during foundation piling. The selection of the final solution to minimize the impact of underwater noise on the marine environment during the construction of the BIII OWF should be made taking into account the type and parameters of the selected foundations and equipment for their installation and the logistics of the process, as well as the need to meet the threshold values of noise levels for marine mammals on the border of the Natura 2000 area Ostoja Słowińska.

In addition, given that the predicted ranges of underwater noise impacts in the form of TTS and PTS in marine mammals and fish from a single impact are up to two orders of magnitude smaller than the ranges of the same impacts from multiple (cumulative) impacts (see Table 1), it can be inferred that the use of a gradual piling procedure (soft start) is effective in protecting these groups of organisms.

Report 2015	The Environmental Impact Assessment Report for the purposes of the procedure finalized by the decision of the Regional Directorate for Environmental Protection dated July 7, 2016, ref. No. RDOŚ-Gd-WOO.4211.12.2015.KP.22
Report/EIA Report	Environmental Impact Assessment Report of Bałtyk Środkowy III OWF

1. Introduction

The section describes the anticipated waste and wastewater emissions at the various stages of the project, which involves the construction of an offshore wind farm designated as Baltic Central III in parameters updated from the variant for which the Environmental Decision was issued. Since this Report is prepared for the purposes of the proceedings to amend the Environmental Decision, thus the Environmental Impact Report-Report 2015, which was the basis for the issuance of the Environmental Decision, is the reference point for both the comparison of alternatives and the basis for conducting the environmental impact assessment. The updated parameters of the BIII OWF are the subject of both the project description and the basis for conducting an environmental impact assessment.

At each stage of the Project, i.e. construction, operation and decommissioning of the BIII OWF, wastewater and waste will be generated. They will be managed in accordance with the applicable law, in particular with the provisions of the Law of March 16, 1995 on the Prevention of Marine Pollution from Ships (unified text, Dz. U. of 2020, item 1955).

According to Article 1. of this law, the provisions of the following international agreements, with amendments in force as of the date of their entry into force with respect to the Republic of Poland, made public in an appropriate manner, shall apply to the prevention of marine pollution by ships:

- International Convention for the Prevention of Pollution from Ships, 1973, done at London on November 2, 1973, as amended by the Supplementary Protocol done at London on February 17, 1978. (Journal of Laws of 1987, No. 17, item 101) and the Supplementary Protocol drawn up in London on September 26, 1997. (Journal of Laws of 2005 No. 202, item 1679), hereinafter referred to as "MARPOL Convention",
- Convention on the Protection of the Marine Environment of the Baltic Sea Area, done at Helsinki on April 9, 1992. (Journal of Laws of 2000, No. 28, item 346), hereinafter referred to as the "1992 Helsinki Convention."
- Convention on the Prevention of Marine Pollution by Dumping of Wastes and Other Substances, done at Moscow, Washington, London and Mexico City on December 29, 1972. (Journal of Laws of 1984, No. 11, item 46), hereinafter referred to as the "Sinking Convention."
- the provisions of the Act of May 15, 2015 on substances that deplete the ozone layer and on certain fluorinated greenhouse gases (unified text: Dz. U. of 2020, item 2065) with respect to the operation on ships of equipment and installations containing controlled substances, where this Law does not provide otherwise.

In addition, the provisions of the Law of December 14, 2012 on waste (consolidated text of the Official Gazette of (t.e.. OJ. U. of 2022, item 699). along with implementing regulations.

The chapter is divided into three parts, corresponding to the stages of construction, operation and decommissioning. Each section describes the activities of the investment, leading to wastewater and waste.

These chapters classify waste in accordance with the provisions of the Regulation of the Minister of Climate of January 2, 2020 on the waste catalog (Journal of Laws of 2020, item 10). Their estimated quantities and expected types of wastewater are also given, along with how they will be handled.

The quantities of waste and wastewater generated from the 2015 Report (Volume II, Section 10: Emissions Waste and Wastewater, SMDI Doradztwo Inwestycyjne Sp. z o.o., April 2015), which is the basis for the Environmental Decision.

It should be noted here that in the variant selected for implementation, which is the subject of this Report, about 70% fewer power plants will be built than envisaged in the 2015 NIS, and twice as many as specified in the Environmental Decision. The use of gravity foundations under power plants has also been ruled out. Thus, it is considered that the Project will not generate emissions and impacts greater than in the 2015 NIS, as well as the variant approved in the Environmental Decision.

2. Waste and wastewater during the construction

Preparatory work for the foundations involves carrying out geotechnical surveys of the seabed to gain a thorough understanding of its geological structure in the areas selected for the foundations. Geotechnical testing typically involves deep drilling and/or CPT (Cone Penetration Test) probing, which involves vertically pressing a probe tipped with a conical tip into the ground at a constant speed and measuring the resistance values on the cone. Specialized drillships or jack-up vessels are typically used for exploration, as well as additional equipment such as ROVs that can be transported on a support vessel. Thus, waste and domestic sewage associated with their work will be generated. No substances will be introduced into the environment during CPT soundings. Drilling may produce small amounts of borings, which will be left on the seabed. As shown by seabed surveys, the seabed is not contaminated (cf. Seabed Survey Report, Section 3 of Volume III), so there is no need to remove them. The ships will generate sanitary sewage, waste (primarily municipal), used work clothes, packaging, cleaners, used lubricants and used oils.

Waste and wastewater will also be generated during the loading, unloading and storage of materials at the construction and assembly port, as well as during the construction process of the power plant and substation itself and the laying of cables, particularly during such operations as:

- the use of ships, helicopters and the work of the farm management center,
- preparation of the bottom by dredgers,
- pile driving or drilling (borings may result),
- injection of cement mortar under the base of the gravity foundation - if such a type of foundation is used for supporting infrastructure,
- connecting individual power plant and station components by means of welding, bolts or adhesives (mainly cement),
- installation of additional elements on the foundations (such as cables and their covers, ladders, etc.),
- placing a layer around the foundation to prevent leaching,
- laying cables in the seabed,
- installation of zinc or aluminum anodic plates to protect them from corrosion,
- storage of excavated material from the installation of foundations and cables.

The expected types and quantities of waste during the construction phase are shown in Table 1 below.

Table 1. Anticipated types and quantities of waste during the construction phase

Code	Groups, subgroups and types of waste	Estimated quantity [Mg/year]
08	**Waste from the manufacture, preparation, marketing and use of protective coatings (paints, varnishes, ceramic enamels), putty, adhesives, sealants and printing inks**	
08 01	**Waste from the manufacture, preparation, marketing and use and disposal of paints and varnishes**	
08 01 11*	Waste paint and varnish containing organic solvents or other hazardous substances	0.05
08 01 12	Waste paint and varnish other than those mentioned in 08 01 11	0.05
12	**Waste from shaping and physical and mechanical surface treatment of metals and plastics**	
12 01	**Waste from shaping and physical and mechanical surface treatment of metals and plastics**	
12 01 13	Welding waste	0.1
13	**Waste oils and liquid fuel wastes (excluding edible oils and groups 05, 12 and 19)**	
13 01	**Waste hydraulic oils**	
13 01 09*	Mineral hydraulic oils containing halogenated compounds	0.05
13 01 10*	Mineral hydraulic oils containing no halogenated compounds	0.05
13 01 11*	Synthetic hydraulic oils	0.05

It is assumed that the quantities of waste at the construction stage of the Project will not be greater than those contained in the provisions of the Environmental Decision.

3. Waste and wastewater at the operation

During the operation stage, waste and wastewater will be generated during the following activities:

- use of ships, helicopters, the farm management center, and social, sanitary and workshop facilities at substations,
- scheduled maintenance and service of farm equipment and facilities,
- unplanned repairs.

The expected types and quantities of waste during the operation stage are shown in Table 2 below.

Table 2. Expected types and quantities of waste during the operation stage

Source: provided by the Contracting Authority

It is assumed that the quantities of waste at the operation stage of the Project will not be greater than those contained in the provisions of the Environmental Decision.

4. Waste and wastewater at the decommissioning

During the decommissioning stage, large amounts of waste will be generated, associated with the physical removal of the farm's components. It is assumed that they will be liquidated as follows:

- power plants - removed in their entirety,
- foundations - removed to a depth of 3 m below the level of the seabed,
- internal cables - removed or left in the seabed, covered by sediment,
- protection against leaching - left,
- power substation - removed or left for future use.

Domestic wastewater will also be generated at this stage - on the decommissioning vessels and at the farm management center.

The expected types and quantities of waste during the decommissioning stage are shown in Table 3 below.

Table 3. Expected types and quantities of waste at the decommissioning stage for 1 power plant

Code	Groups, subgroups and types of waste	Estimated quantity [Mg/year]

Source: provided by the Contracting Authority

At this stage, the model of the power plant, the type of foundation, or the length of the cable sections between each power plant are not known. Therefore, it is not even possible to give an approximate indication of what types and quantities of materials will constitute the main mass of waste during decommissioning. Accordingly, the above table shows estimates for the decommissioning of 1 wind power plant (mass 2500 Mg) sited on a reinforced concrete gravity foundation (mass 7000 Mg), 1 substation (mass 1500 Mg) on a jacket foundation (mass 1500 Mg) and 1 km of power cable section (mass 71 Mg), so that possible recalculations can be made, based on the information contained in the technical description of the farm (Section 3 of Volume II). It should also be remembered that there is a very low probability that the entire farm will be liquidated. Much more likely is the replacement of individual devices, to which the assumptions shown in the table correspond.

It is assumed that the quantities of waste at the decommissioning stage of the Project will not exceed those contained in the provisions of the Environmental Decision.

5. Handling of waste and wastewater wastewater

Contractors for construction, servicing and eventual demolition will be required to store the various types of waste selectively and to separate recyclable waste.

Municipal waste will be collected in plastic bags and then - in a specially marked container.

The operation of the power plant and substation will involve the use of hazardous substances, such as transformer oils (in transformers and reactors, among others), lubricating oils, hydraulic oils, propulsion oils (for emergency diesel generators) or cooling fluids, used in air conditioning systems, and oily water. Hazardous waste will also be generated as a result. Sorbents, filtration materials and spill elimination equipment will be stockpiled on ships and the substation in case of an oil spill. Hazardous waste will be collected separately in lockable, specially marked drums, and then - in transport containers.

Other types of waste will be collected in special containers, bags and containers, in specially designated areas on ships and at the substation.

Once the containers are filled, the waste will be transported to land and transferred to companies with the appropriate permits, for recovery or disposal. The investor will sign relevant contracts with them before the work begins. The farm will have a waste management plan.

The investor will obtain a waste generation permit before starting construction of the farm. Regardless of the amount of waste generated during the construction, operation and decommissioning phases of the project, it is not expected to cause a significant threat to the environment, provided that the provisions of the Law on Waste and related implementing acts are observed.

It should also be noted that according to Article 2(3) of the Law on Waste, the Law does not apply to sediments moved within surface waters for the purpose of managing waters or waterways, managing waters or water facilities, or protecting against flooding or reducing the effects of floods and droughts, reclamation, siltation, land acquisition or treatment, if the sediments are not hazardous. Therefore, sediments removed from the bottom during its preparation for foundation placement are not treated as waste. These sediments are not contaminated, as confirmed by the results of the performed seabed surveys, and it is planned to leave them on the bottom, within the limits of the planned OWF BIII.

During the construction, operation and decommissioning of the wind farm, social and domestic wastewater, oily bilge water, deck washing water and rainwater (including oily water) will be generated.

Social and domestic wastewater generated in the social premises on land will be discharged into the sanitary sewer system or into a tank without a drain, and then to a wastewater treatment plant.

Wastewater generated by the use of bathrooms and toilets located at substations will be treated in biological wastewater treatment plants and then discharged to the sea. Approximately 1 m3 of sanitary sewage is assumed to be generated per day.

Oily water (bilge oil, from deck cleaning, and rainwater) will be collected in the bilges and then treated with oil separators to a level below 15 p.p.m. (as recommended by IMOA 393) and discharged into the sea. Bilge oils (resulting from these processes), on the other hand, were classified as precipitation. They will therefore be collected in special tanks and then collected on land by authorized companies.

OWF BIII / Project	Bałtyk Środkowy III Offshore Wind Farm
EIA	Environmental Impact Assessment
Report/EIA Report	Environmental Impact Assessment Report of Bałtyk Środkowy III OWF

1. Introduction

The section presents a report containing a description of hydrographic conditions and the results of hydrographic modeling of the environment in the area planned for OWF BIII near Slupsk Shoal. The report establishes baseline conditions in the planned Project area, assesses hydrographic impacts in relation to the construction of the BIII OWF, and provides important support in the process of identifying and analyzing the distribution of habitats suitable for marine mammals and waterbirds. The results of the studies and modeling were used as the basis for conducting an environmental impact assessment as part of the proceedings that resulted in the Environmental Decision[1].

Since the total area of the farm that is the subject of this Report, where construction of the power plant is possible, is slightly smaller and within the boundaries of the area described in the Environmental Impact Report for the Central Baltic III offshore wind farm, prepared in 2015, the sections of Volume IV of the EIA Report containing the assessment of the impact on individual receptors cite the results of the studies and analyses from the report that supplements this section - Appendices B.

1. Introduction

The section presents unplanned events that may occur at all stages of the project's "life" (from construction through operation until decommissioning) of the offshore wind farm designated as Baltic Central III in parameters updated in relation to the variant for which the Environmental Decision was issued[1]. Since this report is prepared for the purposes of the proceedings to amend the Environmental Decision, thus the environmental impact report[2], which was the basis for the issuance of the Environmental Decision, provides a reference point both for comparing alternatives and for the basis for conducting an environmental impact assessment. Changes in the description of the project are primarily related to the refinement of the variant approved for implementation, resulting from technological progress, the progress of design work, including the development of a preliminary plan for the farm and the selection of foundation technology and, consequently, the possibility of unplanned events. The updated parameters of the BIII OWF as the variant accepted for implementation result in a reduction of the environmental impact compared to the parameters approved by the Environmental Decision and are the subject of both the project description and the basis for conducting an impact assessment.

According to Article 66 (1) (6) of the EIA, the EIA report should include a determination of the anticipated environmental impact of the analyzed alternatives, including in the event of a major industrial accident and natural and construction disasters (unplanned events).

This chapter analyzes the possibility of unplanned events during the construction, operation and decommissioning of the BIII OWF.

The analysis was carried out in the 2015 Report and applies to both the variant approved by the Environmental Decision and the rational alternative variant, which is also the most far-reaching scenario - NIS 2015, and includes cumulative impacts with the neighboring wind farm - the nature of impacts that could potentially occur in emergency situations is similar, only the scale of risk may differ.

Assessments of the impact of the effects of unplanned events on individual environmental elements can be found in the assessment chapters of the report concerning them (Volume IV). In assessing the significance of unplanned impacts, additional factors were taken into account, i.e. the probability of an event that will be the source of the impact and its potential consequences.

The description is based on the Environmental Impact Assessment Report Volume II, Section 12 Unplanned Events, SMDI Doradztwo Inwestycyjne Sp. z o.o., April 2015, which is the basis for the issuance of the Environmental Decision. The material has been revised and supplemented on the basis of new knowledge and analyses carried out.

[1] Decision of the Regional Director of Environmental Protection in Gdansk RDOŚ-Gd-WOO.4211.12.2015.KP.22 dated July 7, 2017.
[2] Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

2. Identification of hazards and sources of pollution

Unplanned impacts are the result of events or failures that are not related to activities included in the project schedule.

Causes of plant failures that may result in marine pollution may include shipwrecks, collisions of ships with each other and with farm facilities, operator errors, material fatigue, exceeding permissible pressures and stresses, etc.

Based on data from other OWF projects and similar projects, as well as on the knowledge and experience of the study's authors, the following potential unplanned events or failures of the OWF were selected:

- leakage of petroleum substances as a result of a collision, accident or construction disaster (during normal operation or in an emergency);
- accidental release of municipal waste or domestic sewage;
- accidental release of construction materials;
- contamination of the water tone and bottom sediments with antifouling agents;
- explosions of unexploded ordnance of military origin (UXO), either as part of deliberate bottom clearing in preparation for construction or as a result of accidental damage to undetected munitions during the work.

It should be noted that as a result of unplanned events, the abiotic environment, primarily marine waters and, to a lesser extent, bottom sediments, may be directly contaminated. Oil spill events can also affect living organisms that inhabit or otherwise use the seabed, the water table and the sea surface. Explosions of unexploded munitions can cause damage to living organisms in the zone of potential impact or their habitats, as a result of shock wave and noise emissions. Explosions can also cause damage to equipment, including construction or research vessels, and result in contamination of the marine environment with the spills mentioned above.

Each turbine contains a certain amount of mineral oil, the amount of which depends on the size and type of turbine. The following are estimated quantities for the different types of oil that are present in existing turbines installed in marine areas (Strategic Marine Services Ltd. 2011):

- gear oil - 750 - 1000 l/turbine;
- hydraulic oil - 250 l/turbine;
- transformer oil - 1500 -2500 l/turbine;
- lubricating oil - 20 l/turbine.

It can be assumed that an oil transformer in an offshore substation can contain a maximum of about 80$^{m3\ of}$ transformer oil - this is the amount of oil in the largest transformer currently installed at an offshore wind farm in Wlk. Britain[3].

The Baltic Sea is a historically and strategically important body of water for military shipping. Since World War I and World War II, there have been numerous unexploded bombs at its bottom, which pose a significant threat to any seabed intervention activity.

3. Spill of substances oil

During the normal operation of ships during the construction, operation and decommissioning of the farm, spills of various types of petroleum substances (lubricating and diesel oils, gasoline) may occur.

They may contribute slightly to the deterioration of water quality. Heavier oil fractions can be sorbed on the surface of organic and mineral suspensions, which will cause their specific gravity to increase and gradually sink to the bottom. There they can be bound by bottom sediments. However, due to the nature of the sediments in the BIII offshore wind farm area (small amount of organic matter and low content of fine fractions), they will not cause any noticeable deterioration in their quality. It should be assumed that these spills will be small (stage I), up to 20^{m3}. Visible traces of such contamination under favorable conditions can disappear spontaneously due to evaporation and dispersion in the water. The size of these spills will be practically limited to the OWF area.

Pollution of sediments with oil substances will be more noticeable in areas with fine-grained sediments, which have a greater capacity to absorb oil substances.

Oil spills can also occur as a result of a shipwreck or collision, a construction disaster at one of the farm's facilities, and during maintenance work. In the event of a collision or collision between ships, a Grade III spill, i.e. over 50^{m3}, can be expected.

The visible result of an oil spill is the formation of an oil stain, which, under the influence of gravity and surface tension, spreads at a speed that depends on the type of oil and external conditions. The influence of factors such as oil volume, density, viscosity, temperature, wind speed and time determine the size of the spill. The estimated speed of movement of the oil patch in large bodies of water is about 2-3% of the wind speed. It was found that a spill of 1.6 t (1.8^{m3}) of oil in one day of spreading over an area of 1 ^{km2} results in a film thickness of 2µm and a dark color. In contrast, 40 kg of oil results in a spill over an area of 1 ^{km2} with a film thickness of 0.05 µm.

The oil film formed on the surface of the water can cause:

- impeded gas exchange, especially oxygen, between water and the atmosphere,
- a 5-10% decrease in light intensity below the water surface (mainly due to the presence of heavy oil and sulfur fractions) limiting photosynthesis,
- increase in water temperature during the day due to absorption of light rays by the oil layer.

[3] Royal Haskoning DHV, "Polenergia Offshore Wind Developments for projects Middle Baltic II and Middle Baltic III," 2014

At the same time as the spread of the oil slick, other degradation processes run, aiming to reduce the concentration of hydrocarbons on the water surface (e.g., the release of low molecular weight hydrocarbons). Heavier oil fractions, on the other hand, can sorb on the surface of organic and mineral suspensions, which can cause their specific gravity to increase and gradually sink to the bottom. Thus, heavier oil fractions can be bound by bottom sediments, causing contamination. The susceptibility of bottom sediments to contamination depends on the grain size of the sediment and its packing. Loose sandy sediments and fine silty clay sediments are more susceptible to contaminant absorption. Compact clay sediments inhibit the penetration of contaminants deep into the sediment.

3.1. Characteristics pollution

The exposure limit for highly refined mineral oils, according to the Decree of the Minister of Family, Labor and Social Policy of June 12, 2018 on the maximum permissible concentrations and intensities of harmful factors for health in the work environment (Journal of Laws of 2018 No. 1286, as amended), is the Maximum Permissible Concentration (MPC) equal to 5 $^{mg/m3}$.

Typical hazard statements for a wide range of commercial products (diesel, hydraulic, lubricating oils, etc.), based on their data sheets, are presented below[4]:

- R18 - Flammable or explosive vapor-air mixtures may be formed during use,
- R20 - Harmful by inhalation,
- R38 - Irritates the skin,
- R40 - Limited evidence of carcinogenicity,
- N51/53 - Toxic to aquatic organisms; may cause long-term adverse changes in the aquatic environment,
- R65 - Harmful; may cause lung damage if swallowed.

Typical phrases specifying conditions for safe use are shown below:

- S2 - Keep out of the reach of children,
- S23 - Do not breathe vapor/spray,
- S24 - Avoid skin contamination,
- S36/37 - Wear appropriate protective clothing and suitable gloves,
- S51 - Use only in well-ventilated areas,
- S61 - Avoid discharges to the environment. Follow the instructions or safety data sheet,

[4] 4 Classification according to the Council Directive of June 27, 1967 on the approximation of laws, regulations and administrative provisions relating to the classification, packaging and labeling of dangerous substances 67/548/EEC) (http://www.lotos.pl/132/dla_biznesu/reach /characteristics_cards)

- S62 - If swallowed, do not induce vomiting: seek medical advice immediately and show the package or label.

Oils spread over the water surface at a rate that depends on the type of oil and external conditions (wind force, sea state, ambient temperature, etc.). Light oil fractions spread quickly, heavy oils (lubricating oils and greases) tend to clump together. The speed of oil spreading is highest in the initial phase and decreases significantly when the thickness of the layer reaches several millimeters.

The rate of evaporation and the change in composition and concentration of the hazardous substance on the water surface is determined by the substance's vapor pressure. Evaporation, which is a natural process, causes large amounts of light fractions to disappear from the surface of the water, while atmospheric pollution increases and thus fire and explosion hazards appear. In the case of heavy oils and lubricants, evaporation practically does not occur.

The speed of oil spreading is also affected by the formation of an oil-water emulsion with a viscosity greater than that of the oil itself. Spilled oil can quickly disperse in seawater, forming an emulsion that is difficult to break down and contains 40-80% water. The formation of this emulsion, known as "chocolate mousse," is accompanied by a significant increase in viscosity. Emulsification of oil is the result of sea waves, even very calm ones. The process occurs the faster the more agitated the sea is.

Hydrocarbons included in crude oil can be broken down by marine microorganisms. The bacteria that cause this decomposition are most abundant in shallow waters. The degree of biological decomposition of the oil depends on the complexity of its chemical structure, as well as on the presence of suitable media (e.g., nitrogen, phosphorus, oxygen) and the right temperature. Biodegradation occurs at the surface of the water-oil phase separation. Hence, it is advantageous to disperse the oil in as much water volume as possible.

The solubility of oil in water is very low, hence the amount of oil lost in this way is small. Some of the oil, however, may be dissolved by photo-oxidation. Factors that promote photo-oxidation are sunlight and the presence of oxygen. The end result is directly proportional to the surface area of the oil film, while the process itself is very slow and has little effect on oil decomposition. The oil is also partially dissolved through biodegradation. Intermediate products are namely more hydrophilic than oil and dissolve better in water.

The first visible effect of the oil compound spill is the formation of stains on the water body. In practice, oil spreading in offshore waters is formed into long strips separated by clear water, or water covered with a thin oil film. Based on optical observation of the spill, it is possible to determine the thickness of the coating and estimate the amount of the spill - the so-called color code being a fairly precise tool in this regard.

The following table gives the approximate thickness and volume of spills depending on the color of the oil stain, which depends on the thickness of the oil film and thus the refractive index and physical properties of the oil.

Table 1. Calculation of spill size depending on the color of the oil stain

Oil spill color (color code)	Spill thickness [µm]	Approximate spill volume [$^{m3/km2}$]
Silver	0,02 0,05	0.0

Gray	0.1	0.1
Rainbow	0.3	0.3
Blue	1	1
Blue-brown	5	5
Brown and black	15÷ 25	15÷ 25
Dark brown and black	above 100	above 100

Source: Kurc, 2005

The influence of the thickness of the layer after the spill is important in its collection. Thin film spills with low viscosity and low liquidity temperatures are more difficult to collect. The spills, which have a high liquid temperature in the range of 200C, form a thick ooze that is difficult to collect. The best effect is obtained with the additional use of dams that limit the spill area and increase its thickness. In the case of explosion or fire hazards, consideration should be given to whether erecting a dam will increase these risks.

3.2. Qualification of the magnitude of hazards and pollution

The magnitude of the contamination and the scale and scope of the operation can be classified as follows, according to the commonly accepted international system (among others, the ITOPF guidelines), which is shown in the table below.

Table 2. Qualification of the extent of hazards and pollution

Classification	Limit spill size	Description
I degree (small spills)	20^{m3}	Minor spills of petroleum substances that do not require intervention with additional forces and resources, possible to clean up by own means. These are the most common types of spills, caused by minor malfunctions or inadvertent spills, and will be virtually limited to the IMF area. These spills do not cause particular technical difficulties in their removal and do not pose a major threat to the marine environment. Visible traces of contamination under favorable conditions can disappear spontaneously in up to a week due to evaporation, dissipation in water, etc.
II grade (medium-sized spills)	20 - 50^{m3}	Spills of petroleum substances, the scale of which exceeds its own capabilities and requires counteraction at the regional level, which includes activities within the maritime area under the territorially competent director of the maritime office. Such spills are the result of failures of larger units or their collisions, as well as more serious plant failures at the OWF. They require the intervention of forces and resources covered by the National Plan for Combating Hazards and Pollution of the Marine Environment. The decision on the

		required scale of counteraction is made by the director of the maritime office.
III degree (catastrophic spills)	50^{m3}	Spills of petroleum substances having the character of an extraordinary threat to the environment, for which forces and resources under more than one director of the maritime office (including foreign ones) are engaged. The decision on the required scale of countermeasures, expansion or suspension of the rescue operation is made by the director of the maritime office, in accordance with the Law of March 16, 1995 on the Prevention of Pollution from Ships (consolidated text, Journal of Laws of 2012, item 1244).

Source: provided by the Contracting Authority

3.3. Scenarios and risks of possible most serious accidents

The estimated scale of the incident and the maximum quantities released were determined based on the technical concept prepared by Royal Haskoning DHV.

The probability was determined according to Strategic Marine Services Ltd, 2011:

- 10^{-5} - virtually impossible - 1 time in 100,000 years (1/2000 chance of an event occurring in 50 years),
- 10^{-4} - extremely rare - 1 time in 10,000 years (1/200 chance of occurrence in 50 years),
- 10^{-3} - very rare - 1 time in 1,000 years (1/20th chance of occurrence in 50 years),
- 10^{-2} - rare - 1 time in 100 years (50% chance of occurrence within 50 years),
- 10^{-1} - frequent - 1 time per year,
- very frequent - 11 once a year or more often.

3.3.1. Construction and decommissioning phase decommissioning

The predicted scenarios of potential events during the construction and decommissioning stages in the offshore wind farm area are shown in Table 3. The values specified in the estimated scale of the event are the upper limits of the most likely scenario.

Table 3. Events that may occur in the area of the OWF with the determination of the scale and probability of their occurrence - oil pollution (construction and decommissioning stage)

Potential pollution	Potential event	Estimated scale of the incident	Estimated probability of an event and possible countermeasures
Marine gas oil (MGO)	Collision between two	The worst-case scenario envisions the complete	The probability should be estimated as very low, on the order

Potential pollution	Potential event	Estimated scale of the incident	Estimated probability of an event and possible countermeasures
	vessels	destruction of the largest fuel tanks of both vessels and a fuel spill. Assuming that fuel is stored on board in several tanks (filled, as a rule, to no more than max. 3/4 of their capacity), it is reasonable to assume the release of diesel fuel into the environment in the order of 200^{m3} at most.	of 10-4. Any collision of units in the construction/ decommissioning area will occur at a very low speed and the probability that the tanks in both units will be destroyed is extremely low, on the order of 10-5. Use of oil pollution elimination measures available on ships and external forces and resources (SAR).
Marine gas oil (MGO)	Collision of a vessel with an object in the offshore wind farm area	The worst-case scenario is the complete destruction of the vessel's largest fuel tank and its leakage. Assuming that the fuel is stored in several tanks, it is reasonable to assume the release of diesel fuel into the environment in a maximum amount of the order of 100^{m3}.	The probability should be estimated as very low, on the order of 10-4. Use of oil pollution elimination measures available on board and external forces and resources (SAR).
Marine gas oil (MGO)	Stranding of a vessel / sinking	The worst-case scenario is the complete destruction of the vessel's largest fuel tank and its leakage. Assuming that the fuel is stored in several tanks, it is reasonable to assume the release of diesel fuel into the environment in a maximum amount of the order of 100^{m3}.	The probability should be estimated as very low, on the order of 10-5. Use of oil pollution elimination measures available on board and external forces and resources (SAR).
Machine (engine) oil	Collision between two vessels	The worst-case scenario is the complete simultaneous destruction of the largest vessels' oil tanks and an oil spill. Assuming that on large ships the total amount is about 15^{m3}, there will be a release of oil in the order of 30^{m3} at most.	The probability should be estimated as very low, on the order of 10-4. Use of oil pollution elimination measures available on ships and external forces and resources (SAR) .
Machine (engine) oil	Collision of a vessel with an object in the offshore wind farm area	The worst-case scenario envisions the complete destruction of the vessel's largest oil tank and an oil spill. Assuming that on large ships the total volume is about 15^{m3},	The probability should be estimated as very low, on the order of 10-4. Use of oil pollution elimination measures available on board and external forces and resources (SAR).

Potential pollution	Potential event	Estimated scale of the incident	Estimated probability of an event and possible countermeasures
		there will be a maximum release of oil in the order of 15^{m3}.	
Machine (engine) oil	Stranding of a vessel / sinking	The worst-case scenario envisions the complete destruction of the vessel's largest oil tank and an oil spill. Assuming that on large ships the total volume is about 15^{m3}, there will be a maximum release of oil in the order of 15^{m3}.	The probability should be estimated as very low, on the order of 10-4. Use of oil pollution elimination measures available on board and external forces and resources (SAR).
Hydraulic oil	Failure of construction equipment (such as a hose or fitting)	The worst-case scenario envisions the release of oil in the order of 10^{m3} (the maximum amount of hydraulic oil in vessels designed for construction work in offshore areas).	The probability should be estimated as low, on the order of 10-3. Use of oil pollution elimination measures available on board and external forces and resources (SAR).
Hydraulic oil	Operational leaks and spills	Minor oil spills during routine operations, such as when connecting or disconnecting hoses and fittings.	The probability should be estimated as low, on the order of 10-2. Since a hydraulic oil spill will generally occur on deck, the likelihood of the contamination spreading outside the vessel is less - on the order of 10-3. Use of oil pollution elimination agents available on board.
Hydraulic oil	Stranding of a vessel / sinking	The worst-case scenario envisions the release of oil in the order of 10^{m3} (the maximum amount of hydraulic oil in vessels designed for construction work in offshore areas).	The probability should be estimated as very low, on the order of 10-4. Use of oil pollution elimination measures available on board and external forces and resources (SAR).

3.3.2. Stage operation

The predicted scenarios for potential events at the operation stage in the OWF basin area are shown in Table 4. The values specified in the estimated scale of the event are the upper limits of the most likely scenario.

Table 4. Events that may occur in the area of the OWF with the determination of the scale and probability of their occurrence - oil pollution (operation stage)

Potential pollution	Potential event	Estimated scale of the incident	Estimated probability of an event and possible countermeasures
Marine gas oil (MGO)	Collision of a vessel with an object in the offshore wind farm area	The worst-case scenario is the complete destruction of the vessel's largest fuel tank and its leakage. Assuming that the fuel is stored in several tanks, it is reasonable to assume the release of diesel fuel into the environment in the order of 100^{m3} at most.	The probability should be estimated as very low, on the order of 10-4. Use of oil pollution elimination measures available on board and at the OWF site, as well as external (SAR) forces and resources.
Machine (engine) oil	Collision of a vessel with an object in the offshore wind farm area	The worst-case scenario envisions the complete destruction of the vessel's largest oil tank and an oil spill. Assuming that on large ships the total volume is about 15^{m3}, there will be a maximum release of oil in the order of 15^{m3}.	The probability should be estimated as very low, on the order of 10-4. Use of oil pollution elimination measures available on board and at the OWF site, as well as external (SAR) forces and resources.
Gear oil Hydraulic oil Machine oil Lubricating oil	Leak from wind turbine oil system	The worst-case scenario envisions the release of transformer oil in an amount of 2.5^{m3} at most.	The probability should be estimated as low, on the order of 10-3. Since the oil spill will occur inside the turbine, the contamination is not expected to spread outside the facility and contaminate the marine environment.
Transformer oil	Collision of a vessel with an object	The worst-case scenario envisions the release of oil in the order of 80^{m3} at most.	The probability should be estimated as very low, on the order of 10-4. Use of oil pollution elimination measures available on board and at the OWF site, as well as external (SAR) forces and resources.
Transformer oil	Transformer leak at offshore substation	The worst-case scenario envisages the release of oil in the order of 80^{m3} at most (the amount of oil in the largest transformer installed from an offshore wind farm in WK. Britain).	The probability should be estimated as low, on the order of 10-3, directly proportional to the number of transformer stations. Since the spill will occur inside the facility, equipped with a tray with a capacity of 110% of the

Potential pollution	Potential event	Estimated scale of the incident	Estimated probability of an event and possible countermeasures
			transformer oil volume, the contamination is not expected to spread outside the facility and contaminate the marine environment.
Oil (in general)	Incidental oil spill associated with ongoing maintenance and repair work	The worst-case scenario predicts an oil release of $0.2^{m3\ at}$ most.	Probability of 10-2. Use of oil pollution elimination agents available at the OWF site.

As part of the BRISK project (www.brisk.helcom.fi) estimated the risk of a collision in the Baltic Sea area in which more than 5,000 tons of oil pollution would be released into the marine environment (e.g., a tanker cargo unsealing). In the Baltic Sea as a whole, the risk was estimated at 1 case in 26 years, with the most at-risk areas being the Danish Straits (1 case in 65 years) and the Southwest Baltic (1 case in 97 years). For the area of the Southeast Baltic, which may include the BIII offshore wind farm area, the risk of such a collision was estimated at 1 case per 1,060 years, with the most at risk being areas in the area of the Wolin and Rugia islands and the Hel Peninsula. As a result of the BRISK project's risk analyses, ship-to-ship collisions are the biggest threat likely to cause the release of oil pollution, and pose about 100 times the risk of a ship sinking. Fires, explosions on ships and their collisions with installations located offshore (offshore wind farms, platforms, etc.) and oil releases from these installations were considered in the aforementioned risk analyses, but were determined to be much less likely.

Therefore, for the OWF area, the probability of such a collision during construction/ decommissioning, can be estimated as extremely rare and practically impossible, on the order of 10-5.

For comparison, the following analysis is cited, carried out as part of the implementation of the Hornsea 3 offshore wind farm, in the report on the Environmental Assessment of Navigational Risk Assessment in the area of the farm (Environmental Statement, Volume 5, Annex 7.1. - Navigational Risk Assessment, May 2018[5]) it was indicated that between 2005 and 2016 there were 13 accidents involving wind farm components. Of which 1 accident involved a collision during a ship maneuver, and the other between ships operating a farm. The remaining collisions were those of service units related to the operation of individual elements of the farm.

Analyses were also carried out on how the aforementioned farm would affect ship traffic, especially in terms of the gas platforms that exist in its vicinity. It turned out that the implementation of the wind farm as a navigational obstacle would reduce the risk of ship collisions with neighboring platforms, due to the "relegation" of ship traffic to existing shipping lanes that are better regulated.

[5] Available online https://infrastructure.planninginspectorate.gov.uk/wp-content/ipc/uploads/projects/EN010080/EN010080-000582-HOW03_6.5.7.1_Volume%205%20-%207.1%20-%20Navigational%20Risk%20Assessment.pdf access: 03.2022

In contrast, the risk analysis performed on the development of the Teesside Offshore Wind Farm (EDF 2004), located in the North Sea off the central east coast of the UK. Britain (in the Tees estuary with vessel traffic - about 13,000 per year) has shown that the basic measures to be taken to reduce the risk of collision between a large vessel (tanker, ro-ro, container ship) and elements of the farm to ALARP (i.e., acceptable) levels are:

- proper planning of the route in the vicinity of the farm and proper navigation service on the ship,
- control of ship traffic by navigation services (VTS),
- navigation restriction within 500 m of the farm,
- moving the anchorage for small vessels.

3.3.3. The level of collision risk presented in the analysis navigational

In connection with the formal requirements of the permit for the erection and use of artificial islands, structures and devices in Polish maritime areas (PSZW), the Investor commissioned the monitoring of ship traffic in the area of the Baltic Central III offshore wind farm and the so-called navigation expertise. The study was carried out by the Maritime Institute in Gdansk in 2015. The PSZW requires that such an assessment be provided to the permit-issuing authority (the minister in charge of maritime affairs) prior to submission of the ROIA.

It should be emphasized that it is too early in the project preparation process for such a document to meet the formal requirements of a Formal Safety Assessment (FSA), as defined by the International Maritime Organization (IMO). A full and final assessment can be made only at the stage of the construction project, when the parameters of the project, including the actual locations and number of power plants, are known in more detail. Since the technical data of the BIII offshore wind farm available to the investor at this stage was insufficient, the analysis relied, among other things, on the example of the Triton Knoll offshore wind farm from the UK, a project with comparable parameters to the BIII offshore wind farm. Among other things, data were used on the number and traffic of vessels planned to serve this farm, as determined by an analogous navigational expertise.

The analysis for the BIII offshore wind farm in the currently available version was done for the 200 wind turbine variant (which is the furthest-reaching scenario), while the variant selected for implementation will have no more than 60 wind turbines. Several likely scenarios have been analyzed.

Since the baseline data is only an estimate and unverifiable at this stage, this analysis should be considered only as a preliminary document, as the authors emphasize, pointing out that only two of the five steps of the IMO-required FSA have been fully completed. Stage three has been partially implemented. The evaluation contractor was not aware of the relevant parameters determining the construction and operation of the BIII offshore wind farm. Knowledge of these parameters is required in order to determine scenarios and estimate actual navigation safety risks. As a result, it was not possible to identify either specific risk control measures or to group them into risk control options. The analysis contractor was only able to identify hypothetical risk areas.

The preliminary navigation analysis presents higher levels of collision risk than those presented in sections 3.3.1. and 3.3.2. above. The differences in the reported figures are due to their reliance on other source examples. Its summary indicates the following potential impacts of major significance:

1) In the category of incidents referred to as ship collisions:

   a) for fishing vessels, in all scenarios considered, the risks associated with the safety of navigation are in the acceptable area, provided that specific risk reduction measures are introduced for OWF-OSV vessels;

   b) for tankers in one of the scenarios considered (scenario D - construction traffic and operational traffic to 206 farm facilities), the risk level for reasonably likely and rare events is in the ALARP*(As Low As Reasonably Practicable*) area. General risk reduction measures are required[6];

   c) for commercial vessels, in all scenarios considered, the risk level for reasonably likely events is in the ALARP area for consequences described as severe. Risk reduction measures of a general nature are required. For events whose consequences are described as severe, the risk level is in the unacceptable area. Special risk reduction measures are required;

   d) for passenger ships, in all scenarios considered, the risks associated with shipping safety are in the acceptable area;

   e) for service vessels, in all scenarios considered, the risk level for sensibly probable and rare events is in the ALARP area. The probability of a collision is relatively high, but the consequences are of minimal (small ships) or significant (large ships) importance. Due to the high probability, special risk reduction measures are required[7].

2) In the category of incidents defined as contact between a ship and a wind turbine,

   a) for commercial vessels for NIS, the risk level for rare events is in the ALARP area for consequences described as severe. General risk reduction measures are required;

   b) for service vessels for the operational traffic scenario, the risk level for reasonably likely events is in the ALARP area. The probability of contact is relatively high, but the consequences are of minimal (small ships) or significant (large ships) importance. Due to the high probability, special risk reduction measures are required;

   c) for the remaining categories of ships, the risk level is in the acceptable area.

Taking into account the cumulative impact, the collision risk assessment is as follows:

1) in the category of events referred to as ship collision:

   a) for the farm demolition variant (reverse construction traffic scenario), the vast majority of events are in the area of frequencies described as extremely rare. The category of rare

[6] The risk reduction measures mentioned above will be specified in the final version of the navigation expertise, at the stage of obtaining a construction permit.

[7] Source: Monitoring of ship traffic in the area of the OWF Central Baltic II. Final report with impact assessment (navigational expertise), Maritime Institute in Gdansk, 2015, Table 7.1. (Chapter 7.2.)

events includes the probability of head-on and cross collisions for service vessels. Risk reduction measures will be required for large service vessels;

b) for the average operational traffic scenario, the vast majority of events are in the area of frequencies described as extremely rare. The rare event category includes the probability of head-on and cross collisions for commercial vessels and, in one case, tankers. Area collisions for service vessels fall into the category of frequent events, also almost "frequent" may be head-on collision events. Risk reduction measures will be required for all large service vessels. Too many large service vessels will require special security measures. The threat of collision is in an unacceptable area, requiring the search for other solutions;

c) for the high operational traffic scenario, the vast majority of events are in the area of frequencies described as extremely rare. The rare event category includes the probability of head-on and cross collisions for commercial vessels and, in one case, tankers. Area collisions and head-on collisions for service vessels fall into the category of frequent events. Special risk reduction measures will be required for all large service vessels. The threat of collision is in an unacceptable area, requiring the search for other solutions.

2) in the category of events defined as contact between a ship and a wind turbine:

a) the minimum payback period for an event defined as contact between a ship and a wind turbine is 85 years and falls into the category of events defined as rare (this means that this type of event will occur once every 85 years). Thus, for events of this type, there is no cumulative impact effect.

4. Places with the highest risk and particularly vulnerable sensitive

The places with the highest risk, due to the distance from the OWF area and the direction of the spread of pollution, are the Slupsk Shoal and the coastal area oriented between the villages of Rowy and Białogóra, which are tourist destinations, and a small tourist-fishing port in Leba.

Areas particularly sensitive to potential pollution are protected natural areas, including those belonging to the Natura 2000 network, established on the basis of the Law of April 16, 2004 on Nature Protection (consolidated text: (i.e. OJ. U. of 2021, item 1098, as amended).

The BIII OWF will not be located in protected areas, however, it will be located at a distance of about 5.5 km from the Natura 2000 area Slupsk Shoal PLC990001, at a distance of about 8 km from the border of the Natura 2000 areas Przybrzeżne Wody Bałtyku PLB990002 and at a distance of about 19 km from the Natura 2000 area Ostoja Słowińska PLH220023 together with the Słowiński National Park (the Park also includes a sea strip along the shore with a width of 2 nautical miles - the protection perimeter of the Baltic Sea with an area of 11,171 ha).

A sensitive area is also the Baltic Sea coast as a place of rest and recreation, with numerous tourist resorts and beaches between Rowy and Bialogóra.

The locations of the BIII OWF in relation to the nearest sensitive areas are shown in the figure below.

Source: provided by the Contracting Authority

The areas listed above overlap with the sensitive areas identified in the BRISK project (www.brisk.helcom.fi).

The following briefly discusses the closest protected areas established under the Law on Nature Protection of April 16, 2004 (based on Standard Data Forms - SDF).

Slupsk shoal PLC990001

An area of 80,050.3 hectares.

Slupsk Shoal is a body of water in the southern Baltic Sea, encompassing an area with a highly shallow seabed, the boundaries of which are conventionally defined according to the course of the 20-m isobath. It is an area with a highly varied bottom, with numerous hills and depressions. The dominant plants are macroalgae, with many species already disappearing in the Gulf of Gdansk.

Bird refuge of European rank E 79.

No bird species from Annex I of Council Directive 79/409/EEC. During winter there is at least 1% of the long-tailed duck's migratory path population (C3) of the following species: long-tailed duck, guillemot. Wetland birds occur in concentrations of more than 20000 individuals (C4).

Isolated site of habitat 1170 (marine bivalve shoals) in Polish marine waters. The shallows are inhabited by numerous invertebrates, providing a rich food base for the flocks of wetland birds that stop in autumn and winter here.

The dominant plants are macroalgae, with many species found to be disappearing in the Gulf of Gdansk. The site of the crayfish Delesseria sanguinea, which is considered lost in the Baltic Proper.

Coastal Baltic Waters PLB990002

An area of 194,626.7 hectares.

It covers the coastal waters of the Baltic Sea with a depth of 0 to 20 meters. Its borders stretch for 200 kilometers, starting from the base of the Hel Peninsula and ending at the Pomeranian Bay. The seabed is uneven, with denivelations reaching 3 meters.

A bird sanctuary of European rank E 80.

The area is wintered in significant numbers by 2 species of birds from Annex I of Council Directive 79/409/EEC: black-throated diver and red-throated diver (C7). During the winter there is more than 1% of the long-tailed duck's migratory path (C3) population, at least 1% of the guillemot and uhla.

The benthic fauna is dominated by small crustaceans. Rarely observed are large marine mammals - ringed seals Phoca hispida and gray seals Halichoerus grypus, and porpoises Phocaena phocaena.

Ostoja Słowińska PLH220023 and Słowiński Park Narodowy

An area of 32,955.3 hectares.

The area protects the landscape and the diversity of morphological forms observed on the Gardner Spit

- Leba, including unique coastal barchans (up to 40 m above sea level, migrating at a rate of 3 - 10 m per year), the two largest brackish coastal lakes: Lebsko (7140 hectares, max. gl. 6.3 m) and Gardno (2468 ha, max. depth. 2.6 m) along with adjacent meadows, bogs, forests and swamp forests. In total, the area includes: the main complex of the Slovinski National Park (including the marine waters incorporated into the park in 2004), the Rowokół complex and the bed of the Lupawa River connecting Rowokół to the main complex.

In the interduction depressions, known as deflation fields, primary plant succession is observed, running from initial psammophilous communities to crowberry boron.

The area is occupied by well-preserved habitats characteristic of coastal areas, developed typically and over large areas, including 26 habitat types on Annex I of Council Directive 92/43/EEC. In the area, stands of many rare and endangered species have been found, including 23 from Annex II of Council Directive 92/43/EEC, including 8 species of fish, as well as one of the most abundant populations in Poland of the fragrant flax (also a species from Annex II of this Directive) and many vascular plants under legal protection. There are also interesting species of invertebrates in the area, including leeches *Hirudinae*:

Haementria costata, Haemopsis sanguisuga, Piscicola geometra and the arachnids Arachnidae: Arctosa sp., Dolomedes fimbriatus.

A unique landscape of moving dunes is protected here. The marine part of the area is the habitat of the harbor porpoise.

It is an important bird sanctuary of European rank E09 (Slowinski PN). The area is listed as a Ramsar Convention site, and is also within the Slovenian Biosphere Reserve.

There are at least 28 species of birds from Annex I of the Birds Directive, 11 species from the Polish Red Book (PCK). During the breeding season, the area is inhabited by at least 1% of the national population (C3 and C6) of the following bird species: white-tailed eagle (PCK), golden eagle (PCK), osprey (PCK), eagle owl (PCK), dunlin (PCK), variable darter (PCK), ringed plover (PCK); meadow harrier, black cormorant occur in relatively high density (C7).

At least 1% of the migratory route populations (C2 and C3) of the following bird species are present during the migration period: white-tailed godwit (c. 2%), crane (>3%), bean goose (>4%) and barnacle; white-fronted goose and marmot occur in relatively high densities (C7).

Protected status

Slowinski National Park (18,618 hectares, 1967, 29,283.4 hectares as of 2004).

The area includes the Slowinski National Park Biosphere Reserve (18,618 ha; 1967); a Ramsar Refuge: Slowinski National Park.

4.1. Determination of the potential area of the basin covered by the threatened

The extent of oil pollution depends primarily on the amount and type of oil spilled, hydrometeorological conditions such as wind strength and direction, sea state and its surge, water and air temperature.

The degree of dispersion of oil droplets in seawater is also not insignificant. In calm seas, about 40% of the oil remaining on the surface can penetrate deep into the water mass during the first few days, while up to 95% during storms. Dispersion, however, results in contamination of the food chain in the failure area (Malaczynski 2010).

Oil pollution travels on the sea surface with the resultant velocity for the speed of the water surface layer, forced by wind action, and the speed of sea currents. Any change in these parameters causes changes in the shape of the spill. Most often, it is a set of separated patches on the sea surface with an irregular shape, moving in the direction of the wind at 3-4% of its speed, having a thickness of <1 mm, width of up to 1 km and length of up to a dozen km. When the hydrometeorological situation is unfavorable, the speed of movement ranges from 0.5 to 2.0 km/h (Malaczynski, 2010). If strong currents are present along the shore, pollution can occur.

Appendix 1 of this section presents the estimated potential extent of oil pollution for selected input parameters, based on the UMPL mesoscale atmospheric model (Pietrek, 2006) and the two-dimensional stochastic model of oil pollution spread (Mazurek 2013).

The maps show the potential extent of the oil spill for the most unfavorable scenario, i.e. the release of about 200$^{m3\ of}$ oil pollution after 1-24 hours (the volume of the spill mainly affects the thickness of the oil layer on the water surface, but to a lesser extent its extent, which depends mainly on sea currents and wind direction), for the following options:

A. Release in the geometric center of the IMF

   1) any wind direction of up to 2°B and the speed of surface currents up to 15 cm/s, and moving the spot for the most likely wind direction;

   2) any wind direction of up to 3°B and the speed of surface currents up to 30 cm/s, and moving the spot for the most likely wind direction;

   3) taking into account the wind distribution for the Southern Baltic for winds up to 2°B and surface current speeds up to 15 cm/s;

   4) taking into account the wind distribution for the Southern Baltic for winds up to 3°B and surface current speeds up to 30 cm/s.

B. Release on IMF border

   1) taking into account the wind distribution for the Southern Baltic for winds up to 3°B and surface current speeds up to 30 cm/s.

Modeling of the extent of the oil spill patch was based on a factor of 0.030 - 0.035 of the patch's velocity relative to the wind measured at 10 meters above sea level.

The center circles represent the likely extent of the spill at any wind direction, while the outline of the spill shows an example of the likely extent of the spill at a particular wind direction - the effect of the Coriolis force deflecting the direction of the spill to the right has been taken into account.

In the case of maps showing the velocity of the spot moving at 30 cm/s, it should emulsify and disappear after 12-18 hours of drifting on the surface - its significant environmental impact should not exceed the ranges of the maps calculated for a velocity of 15 cm/s (for light fuels, which evaporate faster and emulsify heavy fractions).

The map, which takes into account the wind rose for winds of 3□B, determines the modified probability of an oil patch in specific directions in the case of a point spill, as well as the danger resulting from its occurrence at the border of the OWF area (e.g., a collision on the outer strip of a body of water) - it shows the most likely maximum area of spill danger.

The presented oil pollution extents have been determined on the basis of wind statistics, as determined by UMPL model predictions and maximum current velocities in the area (about 30 cm/s, Krzyminski 1996), but other scenarios, corresponding to other meteorological conditions prevailing at the time, but statistically less likely, are not excluded. It will only be possible to determine the actual extent practically during the event, based on current meteorological data and the type and potential amount of pollution.

4.2. Description of the methods used to remove pollution

The primary methods of eliminating oil spills are:

- eliminating the source of the spill,
- mechanical collection from the surface of the water, after limiting the spread of the spill,
- sorption,
- dispersion,
- combustion.

The most environmentally beneficial method, with virtually no side effects, is mechanical oil collection.

Dispersing involves the use of chemicals (dispersants) that help disperse the oil and accelerate its biological decomposition. However, in accordance with §6 of the Decree of the Council of Ministers of August 30, 2017 on the organization and manner of combating hazards and pollution at sea (unified text Dz. U. of 2022, item 216), the use of methods other than mechanical is restricted in Polish maritime areas and requires the consent of the competent director of the maritime office.

The other methods (sorption and incineration), due to their low efficiency and environmental nuisance, are not practically applicable in the area under study.

Typical equipment used for mechanical collection in marine conditions are:

- plastic flexible dams, shape-shifting in all planes and along their length and height under the influence of waves, tows and currents;
- rigid dams as structures with floats, with limited shape variation under external influences - more effective than flexible dams, but can be used when the sea state does not exceed 1B and the speed of the surface current is less than approx. 1.5 m/s;
- sorption dams - sorbent sleeves made of mesh filled with natural or artificial sorbent;
- adhesive collectors, which take advantage of the better adhesion of oil to certain materials, but do not soak with it (e.g. metal or plastic discs, ropes, belts, etc.);
- overflow-pump collectors, which mechanically separate oil from water using a threshold placed at the level of the oil-water separation surface;
- vortex collectors, which use the phenomenon of a vortex produced by a horizontal disc placed under water and causing oil to flow into the suction pump.

Specially designed sweep nets can be used to collect heavy lubricating oils and greases that tend to clump together in conglomerates.

The spill control action can be divided into the following stages:

1) Location and fencing of the spill. The dam should be set up so as not to create problems with pumping out the water-oil mixture and allow the oil to flow down to the collection area. Take into account the direction and speed of winds and currents. If there is a large spill, additional safety dams should be set up especially on the leeward side (several dam lines). The dam should be towed at the right speed, i.e., at a speed that will not cause it to break or waterlog. In the case of spills from ships, the dam should be set up so that the distance between the dam and

the ship is such that the oil does not flow outside the dam. A dam length of at least 3 ship lengths is recommended.

2) If possible, remove from the spill site all vessels that may impede the spill control operation. However, the vessels at the center of the spill are not being removed - it is advisable to remove the crew of these vessels and stop all work in the danger zone. In the event of a fire hazard, it is necessary to evacuate all workers in the vicinity of the contamination zone.

3) Removal of stains with the highest density of oil fraction (thickest oil layer).

4) Cleaning of hard-to-reach areas containing a significant amount of oil.

5) Removal of the remaining oil stains, cleaning the water surface by collecting the remaining trace amounts of oil that were not removed by collectors through, for example, the use of sorbents, cleaning of IMF equipment and facilities and ships.

6) Disposal of waste generated from the liquidation of the spill (oil/water mixture/emulsion, contaminated sorbents).

7) Cleaning of the equipment used during the action, completion of the action.

8) The use of methods other than mechanical methods (i.e., mechanical collection) for combating pollution in Polish maritime areas may take place only with the consent of the competent director of the maritime office (§6 of the Decree of the Council of Ministers of August 30, 2017 on the organization and manner of combating hazards and pollution at sea).

4.2.1. Liquidation of spills under conditions winter

Low temperatures reduce fire and explosion hazards. As oils increase their viscosity, they become less mobile. Less volatile substances evaporate into the atmosphere. Where the surface of a body of water is covered by a solid layer of ice, pollutants have no way of getting under the ice when spilled from above, while they cannot escape to the surface when they get onto the unfrozen surface of the sea.

Snow acts as a sorbent. The oil that has made its way into the waters between the ice and snow crystals is partly retained there and partly spreads on the surface of the water. The ability to spread is limited by increasing viscosity.

To capture the tethered contaminant, the entire contaminated mass must be collected and transported ashore to a designated location for oil extraction. This can be done by melting the mass in properly prepared and heated tanks. Capturing such a mass of ice, snow and dirt requires clearing a sizable body of water of ice and setting up conventional floating dams, taking into account the phenomenon of free movement of contaminated ice in the depths. As a rule, this requires duplicating and even triplicating the contamination capture system.

4.2.2. Elimination of spills during storm

In rough seas and stormy conditions (sea state above 6°B), mechanical collection is impossible - there will be a strong dispersion of oil contaminants in the ocean depths, promoting biodegradation and

limiting the possibility of oil splashing. There will also be an increase in oil viscosity as a result of emulsification and evaporation of lighter fractions.

The dissipation of the oil will occur naturally, within a few to several days.

Technical activities can be conducted in the full range up to and including 3°B, at 4-6°B they can be conducted to a limited extent, while above 6°B they will not be possible.

5. Accidental release of municipal waste or wastewater domestic

During the construction of the wind farm, waste, mainly municipal and other waste not directly related to the construction process, as well as domestic sewage, will be generated on vessels as well as at the construction facilities located on land (at the port serving the project). Their expected types of quantities, as well as how they will be handled, are presented in Section 10 of Volume II of the EIA. Waste and wastewater can be accidentally released into the sea when picked up from ships by another vessel and in the event of an accident, causing a local increase in nutrient concentrations and deterioration of water and sediment quality. However, the pollutants should quickly disperse, so they will not contribute to permanent deterioration of the environment in the project area.

As a minimizing measure, it is recommended to create procedures related to waste and wastewater handling.

6. Accidental release of chemicals and waste from construction, operation or decommissioning of the farm

During the construction of the wind farm, waste directly related to the construction process will be generated on vessels, at construction facilities located onshore (at the port serving the project) and at the project site. These can include damaged parts of the farm's assembled components, cement, grout, mortar, binders used to join the foundation and power plant components, and other chemicals used during construction work. They can be accidentally released accidentally into the sea.

The bulk cement is packed in bags of about 1^{m3}. It was assumed that single incidents involving the sinking of about $5^{m3\ of}$ product could occur during handling.

Grouts, mortars and other binders often contain hazardous substances. They are characterized by different chemical compositions, depending on the manufacturer. E.g., epoxy (two-component) grouts contain in various proportions: epoxy resin, alkyl glycidyl ethers, polyamines. Once they enter the water depths, due to their high density of about 1.3 g-cm-1, they sink and are deposited on the bottom. The above substances do not pose a major threat to human health and life, but they are considered a serious threat because they cannot be easily removed from the bottom and are toxic to marine organisms. The scale and estimated probability of their release (determined in accordance with Strategic Marine Services Ltd, 2011, see Section 3.3.) are estimated in the table below.

Table 5. Events that may occur in the offshore wind farm area with an indication of the scale and probability of their occurrence - construction materials

Potential pollution	Potential event	Estimated scale of the incident	Estimated probability of an event and possible countermeasures
Grout, mortar, cement, grout, etc. containing substances toxic to the marine environment	Reloading in powder form	The powdered products will be transshipped by crane from the supply vessel to the platform in unit packs of about 1^{m3}. It is expected that about $5^{m3\ of}$ product may sink during handling.	The probability should be estimated as low, on the order of 10-2. Use of external companies specializing in underwater work.

Source: provided by the Contracting Authority

During the operation of the farm, maintenance of its facilities will be carried out (cf. description of the construction phase, Volume II Section 5 of the EIA). Accidental release of small amounts of waste or operating fluids into the sea cannot be ruled out.

During decommissioning of the farm, it seems inevitable that bottom sediments will be contaminated with waste from the process. The magnitude of this impact will depend on the method adopted for carrying out these works (cf. description of the decommissioning stage, Volume II Section 6 of the EIA), and the greatest pollution may occur if the gravity foundations have to be crushed.

The anticipated types and quantities of waste are presented in Section 10 of Volume II of the EIA.

For this type of investment like an OWF, a detailed plan is generally developed to address risks and pollution arising during construction, operation and decommissioning of the OWF, which specifies minimization measures and how to deal with such events. **It is recommended that such procedures be created as a minimization measure.**

If the contaminating substance sinks quickly (e.g., grout, mortar, grout joints, etc.), there will be no need for mechanical dams. In this case, it is necessary to determine the area (taking into account the direction and speed of the sea current), on the bottom of which contaminants have settled, in order to remove them later. In shallow waters it is possible to use mechanical and pneumatic mining equipment, as well as manual, using diving teams. In any case, these operations are tedious and costly.

7. Contamination of water depths and bottom sediments with agents antifouling

To protect the hulls of ships from overgrowth, biocides are used, which may include, for example, copper compounds, mercury compounds, organotin compounds (such as tributyltin - TBT). These substances can pass into the water's depths and eventually be retained in the sediment. It should be assumed that the emission of these compounds will be limited by dilution in the water depths. Of the substances listed, organotin compounds are the most harmful (toxic) to aquatic organisms. TBT (the most harmful substance) is currently banned in antifouling paints, but the presence of these compounds in older units cannot be ruled out. The sensitivity of seawater and bottom sediments to biocides released from hulls was determined to be medium.

As a minimizing measure, it is recommended that vessels whose hulls have not been coated with TBT-containing antifouling paint be used at any stage of the project. This will eliminate this most harmful impact on aquatic organisms.

8. Management of unexploded ordnance of military origin military.

Due to the potential risk of negative impacts on people and the marine environment due to damage and explosions of remnants of combat equipment and munitions on the seabed, the Investor is taking measures to minimize these risks. As part of the UXO management strategy, the Investor has planned a series of activities, some of which have already been implemented in the preparation of the BIII OWF project to date.

Table 6. Key steps in the risk management strategy for unplanned UXO explosions

Stage	Description	Status / dates
1	UXO documentation study for preliminary assessment of the threat in question	Completed
2	Preliminary inventory to clarify the recognized conditions in the Project area and preliminary selection of potentially hazardous objects for detailed recognition	Completed
3	Detailed assessment of the risk posed by UXO to determine the threat from UXO and chemical weapons and the level of tolerance against them in the implementation area	Completed
4	Specialized inventory of UXO, which will result in geophysical maps of the seabed in the vicinity of the pipeline route and final identification of potential UXO in the construction area	Scheduled, will take place before construction work
5	Safeguarding UXO identified within the boundaries of the construction area	Scheduled, will occur before construction work

The first analysis of the potential threat of UXO in the Project area (documentation study) and preliminary inventory was carried out as part of the research campaign in 2012-2013, when a literature and museum data search) and seabed surveys (see Volume III Section 3) were conducted.

As part of the survey, the image of the bottom of the BIII offshore wind farm was constructed line by line from 217 profile lines representing 220% of the coverage of the farm area, for the most accurate inventory of objects on the bottom. In the course of the task, the analysis of sonar images taken on profiles with a total length of 2,500 km was carried out. The recorded sonar data was geometrically corrected and rectified, then arranged into a sonar mosaic that creates a clear picture of the bottom. Based on it, 218 points were pre-determined, from which, after reducing the buffer zone, 54 points were selected for verification with the ROV, which were small objects visible on the bottom (potential UXO). After ROV analysis, no objects of a military nature were found with particular reference to torpedo and mine weapons. This does not mean that there are no remnants of these weapons, unexploded ordnance and chemical weapons in the area.

Tests of sediment chemistry and water showed no elevated indicators that could indicate the presence of chemical weapons residues in the sediment. However, it must be remembered that these studies were conducted point-wise and their coverage is local, giving an idea of the overall picture of sediment and water chemistry in the BIII offshore wind farm area.

In 2018, the Investor commissioned Ordtek Limited to perform a UXO risk analysis of the farm area along with a mitigation strategy[8]. The analysis performed confirmed the highly unlikely occurrence of most types of mines used in the Baltic during WWI and WWII, as well as land munitions in the farm area. The possibility of World War I Axis mines (4 German minefields have been recorded within 7 km south of the farm area), as well as the presence of torpedoes, rockets and naval munitions, both from the war and post-war periods, were considered unlikely. The presence of chemical weapons was identified as a possibility - possible drop and dump sites for chemical weapons were located 18 km south of the Project boundary and 19 km to the north. As part of the risk mitigation strategy, it has been recommended to conduct geophysical surveys using a side scanner and Multibeam echo sounder, and to obtain ALARP certification before conducting geotechnical surveys for the preparation of the BIII OWF project.

These recommendations were implemented in 2018 prior to the initial geotechnical campaign at the indicated geotechnical drilling sites. After a survey campaign to look for UXO, ALARP certificates were issued based on the data collected, thus finding no UXO in these locations.

The above measures will be repeated before the next stage of geotechnical studies, and before construction work begins. The purpose of the inventory will be to develop a comprehensive, detailed and definitive proof of the absence of UXO within the boundaries of the farm and in the zone of ongoing works. Inventory tasks include:

- geophysical surveys (with a magnetometer or gradiometer) of the entire pipeline installation corridor (and other areas relevant to the project) with a grid density that gives sufficiently detailed data;
- surveys by unmanned underwater vehicle of objects selected as "potential UXO" (pUXO), including possibly pUXO possibly buried in the seabed, with visual confirmation of whether the objects so surveyed are in fact UXO.

The result of the study will be the identification of actual UXOs that need to be secured.

If at the stage of specialized UXO inventory is confirmed the presence of UXO within the boundaries of the area of investment works, it is envisaged to implement special protection of UXO before the commencement of works:

- an exclusion zone will be delineated around each UXO mapped but not visually inspected by an unmanned underwater vehicle - with boundaries and size depending on parameters specific to local risk and surrounding seabed conditions. The exclusion zone is intended to protect the facility from shrugging;

- a safety zone will be delineated around each UXO identified as such - with boundaries and size depending on parameters specific to local risk and surrounding seabed conditions. The safety

[8] Unexploded Ordnance (UXO) Hazard and Risk Assessment with Risk Mitigation Strategy, Baltic II & III Offshore Wind Farms, Ordtek Limited, 2018

zone is intended to protect the investment and third parties, ships and equipment in case the facility explodes.

The risk of having to remove unexploded ordnance can be mitigated, as far as practical, by relocating the various components of the OWF so as to avoid unexploded ordnance and unexploded ordnance visible on the seabed. If this approach is not feasible, UXOs will require decommissioning by removal from the seabed or detonation. It is assumed that the unexploded ordnance can be removed from the bottom, transported to land and disposed of in a controlled manner there. According to the OWF design strategy, it is assumed that the decommissioning of UXO will be an unplanned task.

It is deliberately planned to conduct the last parts of the detailed UXO inventory at a fairly late stage of the process preceding the geotechnical investigation and then the construction process. This is because there is a risk of objects on the seabed being dragged into the farm construction area by, for example, trawling with fishing nets, as well as the risk of changes in the seabed surface due to seasonal phenomena and storms. ALARP certificates for UXO are valid for only six months due to the possibility of changes in the image of the seafloor and the appearance of new objects there in the meantime.

Unplanned event (liquidation of UXO) - security measure

If UXO removal proves necessary, such activities could affect fish and marine mammals at the individual level. This is because the detonation of conventional weapons residues will be a source of underwater noise and vibration emissions.

Underwater explosions are among the strongest sources of sound in the sea. The characteristics of sound propagation underwater depend on the time of year, bathymetry and the size of the charge that is exploded. According to noise propagation modeling from potential explosions associated with UXO bottom cleaning, performed for the Baltic Pipe pipeline impact assessment within Polish marine areas (SMDI/Ramboll 2019), the ranges of impacts on fish and marine mammals (mortality, permanent hearing loss ("PTS"), temporary hearing threshold reduction ("TTS")), with detonation of the largest cargoes of 950 kg TNT, can reach no further than 20 km from the explosion source. Sample data is presented in the table below.

Table 7. Limiting distances from the source of the UXO explosion relative to the thresholds of sensitivity of fish and marine mammals to underwater noise impacts

Detonation of unexploded ordnance		Threshold value	150 kg TNT		950 kg TNT	
			Summer	Winter	Summer	Winter
Receptors	Impact	SEL (Cum*) [dB re 1µPa2s]	[km]	[km]	[km]	[km]
Seals and porpoises	PTS	179 dB	4.0	3.4	6.5	5.6
	TTS	164 dB	13.9	12.8	18.7	17.4
Fish	Mortality (fatal injuries)	207 dB (229-234 dB peak.)	0.6	0.6	0.7	0.7
	Physical injuries	203 dB	0.7	0.7	0.7	0.7

9. Ways to prevent pollution

9.1. Construction and decommissioning phase decommissioning

The following are the most relevant technical and organizational safeguards for pollution prevention during construction and decommissioning of the OWF:

- closure of the body of water covered by construction/liquidation works for vessels not related to the construction/liquidation of the OWF;
- the use of vessel warning systems not related to the construction/ decommissioning of the OWF;
- definition of safety zones in the mode of navigational warnings of the national coordinator (KKON), which is currently the Hydrographic Office of the Navy in Gdynia (KKON operates within the framework of the World Navigation Warning System); these zones and their range are defined by an order of the Director of the Maritime Office on the basis of the Act of March 21, 1991 on maritime areas of the Republic of Poland and maritime administration (consolidated text Dz. U. of 2022, item 457); e.g., for oil rigs, the safety zone includes the area of a circle with a radius of 500 m around the point of its foundation - in the case of wind power plants, these will be the distances from the corners of the body of water designated for the OWF;
- designation of waterways for vessels associated with the construction/ decommissioning of the OWF in order to minimize potential interactions between the movement of vessels serving the farm and external vessels, as well as to control access (e.g., by designating the entrance to the area) and vessel traffic in the area of the OWF;
- determining the maximum permissible speed of vessels in the OWF area and their mutual minimum distances from each other (depending on the type and size of vessels, meteorological conditions, etc.);
- introduce a requirement for a minimum of 2 people to be present on the bridge of the vessel associated with the construction/ decommissioning of the OWF, in order to reduce the risk of navigational error;
- audited service time control systems;
- systematic update of the development of the OWF area (the degree of erection/ decommissioning of facilities, routing of cable lines, etc.);
- equipping a minimum of one vessel in the offshore wind farm construction/ decommissioning area with flexible dams and packaged sorbents to limit the spread of oil spills and for the elimination of small spills, as well as a device for collecting mechanical contamination from the water surface (e.g., a skimmer) with a tank(s) for the collected oil;
- developing procedures for the movement and storage of substances that may contaminate the marine environment;
- establish a system of effective communications in the system: IMF - Contract Engineer - Services responsible for the safety of navigation and counteracting marine hazards and pollution, in

order to quickly respond to emergency situations (defined in the plan and accepted by all participants, i.e., the maritime administration, the Maritime Search and Rescue Service (MSPiR), the Contract Engineer, the investor and others). It should be noted that in the current state of law, the Ordinance of the Council of Ministers of August 8, 2017 on the organization and manner of combating hazards and pollution at sea (unified text Dz. U. of 2022, item 216).

- does not oblige offshore wind farm operators to develop plans to combat hazards and pollution;
- regular training and coaching of employees and subcontractors, including in the prevention and elimination of oil spills;
- informing the crews of small vessels about the dangers of wave action caused by large vessels and the associated uncontrolled behavior that can result in a collision with an OWF facility.

Most of the proven standards that will be used for the proposed development have been developed by the oil industry for offshore oil platforms. Thus, they will be taken into account when analyzing the risks and management methods for the construction of the Central Baltic III offshore wind farm. The best benchmark that is widely recognized in the market and hence its solutions can be implemented is the American Petroleum Institute (API) guidelines "Recommended Practice for Planning, Designing and Constructing Fixed Offshore Platforms- Working Stress Design" (API 2007) and "Operation and Maintenance of Offshore Cranes" (API 2003). If it is necessary to detonate unexploded conventional weapons, it may be necessary to apply safety measures, which are summarized in the table below (Table 8).

Table 8. Suggested safeguards in case of UXO liquidation

Receptor	Safeguard measure (unplanned event)
Fish	**Sonar survey** It is necessary to identify by sonar survey from the deck of a technical vessel whether fish form shoals in the area to be secured and, based on their presence or absence, determine whether to proceed with the elimination of UXO or wait with detonation for a more appropriate moment. The assessment is expected to secure groupings of fish populations that may occur in the vicinity of UXO.
Marine mammals	**Securing marine mammals** The overall plan for securing marine mammals from UXO includes measures to protect these animals, such as the work of marine mammal observers ("MMO"), passive acoustic monitoring ("PAM"), and sound deterrents. **Visual observation and PAM** Visual observation by the MMO will be carried out from the deck of the surface vessel (using a suitable type of observation platform). Visual surveillance will be limited to daylight hours and only in conditions of good visibility, as visibility decreases as the weather deteriorates and with the twilight season. If marine mammals appear in the vicinity of UXO before its scheduled decommissioning, the detonation will have to be rescheduled.

	Visual observation prior to the disposal of unexploded munitions/ERW does not guarantee the complete safety of marine mammals at the time of detonation - these animals may be underwater, out of sight of observers, and for a long time. However, a visual inspection of the area just before the intended removal of UXO can save those animals that manage to be spotted from harm and death. PAMs are hydrophones placed in the water column. The underwater sounds they detect are processed by specialized sound processing software. PAM is a means of supplementing visual observations by MMO. Seal repellent Seal repellents are sound deterrent devices. The plan is to use them to scare away seals and porpoises, chasing them far enough away from the sites of necessary UXO removal. The range of operation, i.e. the effectiveness of these devices depends on their type and operating configuration. It is known that porpoises are easier to chase away with deterrents than seals (Hermannsen et al. 2015).

The types of other safeguards and issues that will need to be addressed in the implementation of the investment will depend on the results of a detailed risk assessment.

In the event that it is necessary to remove UXO, during the construction process, which were not identified during the pre-completion surveys (unplanned event), the farm contractor will use implementable measures to minimize the risk of impacts on fish and marine mammals (e.g., observation, deterrence).

9.2. Stage operation

The following are the most relevant technical and organizational safeguards for pollution prevention during the operation of the OWF:

- sealed turbine housing to prevent any oil spills from reaching outside the facility;
- offshore transformer stations will be equipped with oil pans with a capacity of about 110% of the amount of oil in the transformers, capable of accepting a complete spill in the event of a leak;
- the use of a system that controls the operation of the plant and the condition of the facilities, reacting in advance to possible damage to the plant and allowing, for example, to change the operating parameters or shut down the equipment before a more serious failure occurs resulting in, among other things, the release of oil;
- definition of safety zones in the mode of navigational warnings of the national coordinator (KKON), which is currently the Hydrographic Office of the Navy in Gdynia (KKON operates within the framework of the World Navigation Warning System); these zones and their range are defined by an order of the Director of the Maritime Office on the basis of the Act of March 21, 1991 on the maritime areas of the Republic of Poland and maritime administration

(consolidated text Dz. U. of 2022, item 457); e.g., for oil rigs, the safety zone includes the area of a circle with a radius of 500 m around the point of its foundation - in the case of wind power plants, these will be the distances from the corners of the body of water designated for the OWF;

- determination of the maximum permissible speed of vessels in the area of the OWF;
- within the offshore wind farm to require a minimum of 2 people on the bridge of the vessel, in order to reduce the risk of navigational error;
- audited service time control systems;
- equipping the OWF with flexible dams and packaged sorbents and a small/medium sized mechanical collector (e.g., skimmer) along with a tank(s) for collected oil, in order to limit the spread of oil spills and for the elimination of small spills (located in one of the offshore transformer stations);
- 24-hour supervision of the operation and monitoring of the IMF by the IMF Operations Center;
- developing procedures for the movement and storage of substances that may contaminate the marine environment;
- establish a system of effective communications in the system: OWF Operations Center - Services responsible for the safety of navigation and countering marine hazards and pollution, in order to quickly respond to emergency situations. It should be noted that in the current state of the law, the current Decree of the Council of Ministers of December 3, 2002 on the organization and manner of combating hazards and pollution at sea does not obligate offshore wind farm managers to develop plans for combating hazards and pollution;
- regular training and coaching of employees and subcontractors. among other things, on the proper handling of OWFs and the prevention and elimination of oil spills;
- optionally, implementation of ISO 9001:2000 quality management system certification (or equivalent) by the MFW operator.

The most important guidelines for the efficient and safe operation of an offshore wind farm are set forth by the Danish Energy Agency in its Guidelines for the Design, Production, Installation, Operation and Maintenance of Wind Turbines (DEA, 2008). The model for managing and monitoring the operation of the Central Baltic III offshore wind farm may be based on these guidelines or others more current at the time of commissioning the farm.

9.3. Measures to minimize negative impacts on shipping maritime

The following are measures to minimize negative impacts on marine navigation, as recommended by the navigational analysis[9] (see Section 3.3.3), performed as a result of the implementation of the PSZW

[9] Monitoring of ship traffic in the area of the OWF Central Baltic II. Final report with impact assessment (navigation expertise), Maritime Institute in Gdansk, 2015, Chapter 9.

recommendations for the BII OWF. The document states that the OWF will affect existing and planned shipping routes and maritime traffic regulation systems to the following extent:

- an increase in vessel traffic in the vicinity of the project site and adjacent areas;
- increase ship traffic on the shipping route of the TSS Slupsk Shoal in traffic transverse to natural navigation;
- restrictions on shipping and fishing activities
- increasing the intensity of maritime radio communications;
- potential disruption of maritime events, recreational shipping near the ports of Leba and Ustka, or non-commercial fishing activities.

Potential negative effects caused by the aforementioned factors include increased likelihood of a maritime accident, impact on port operations, possible pollution, injury or death of personnel personnel. In addition, increased intensity in maritime radio communications can affect the coordination of missions, pilot activities directed by the Coast Guard, emergency services, etc.

The main measures to minimize the negative impact of the BIII OWF at all stages of the project are proper navigational signage. In addition, it is recommended:

- establishment and maintenance during the stages of operation and especially decommissioning of properly marked safety zones;
- closure of navigation in the construction area during the construction and decommissioning phases, and establishment of the BIII OWF area with the adjacent safety zone as a hazardous area for navigation to be avoided (area to be avoided) during the operation phase;
- establish an absolute ban on sailing in the 50-meter zones around each structure of the BII OWF;
- introduce direct navigational surveillance during the construction and decommissioning phases, and monitoring of the BIII OWF area during the operation phase using navigational surveillance vessels, closed circuit television (CCTV), the Automatic Reporting System (AIS) and radar;
- providing navigational support in the form of AIS transponders, RACON radar transponders, navigation lights and foghorns on key turbines;
- launch of a navigation service covering ships in the vicinity of the BIII OWF (notifications of entry, approach to the closed area).
- development of rescue plans and training of ship crews participating in the construction of the BIII OWF and its operation;
- regularly updating and checking through exercises the rescue plans;
- provide permanent lines of communication between the BIII offshore wind farm and the onshore operation supervision center, as well as communication with the navigation supervision service (Slupsk Traffic Control) and the Maritime Search and Rescue Service (MSPiR, SAR);

- development and agreement (including public) of plans for safe construction, operation and decommissioning of the BIII OWF.

A potential minimization measure that will reduce the potentially negative impact of the OWF at all stages of the project is to continuously inform stakeholders and the public through the publication and broadcast of local announcements (NTMS) in cooperation with the captains of nearby ports and the maritime border service, as well as the introduction of navigation charts with the project area marked. In situations involving the work of SAR or maritime border services, communication and the possible introduction of routine exercises should be developed. An additional potential minimization measure is the designation of a temporary safety zone around the construction site, which would reduce the risk of ship collisions by temporarily ordering vessels to avoid the construction area. In addition, minimizing potential impacts can be achieved by constantly monitoring weather conditions. Weather observations will enable rapid and safe mobilization and demobilization of vessels working in the project area, which will ultimately reduce the risk of possible accidents related to the construction, operation and decommissioning process.

10. Information on the organization of response to accidents of hazards and pollution of the environment marine

The International Convention MARPOL 73/78 requires all ships, ports and harbors to inform the relevant services of all incidents of marine pollution.

It is important to determine the size of the spill and its classification (in grades I-III). Weather and sea state are important factors in determining decommissioning strategies. In the event that unidentified pollution is found flowing into the area of the OWF basin, classification and information procedures will be applied, but the cost of its elimination will be covered by the polluter or, if it cannot be identified, by the State Treasury (in accordance with the National Plan for Combating Hazards and Pollution of the Marine Environment).

11. Organizational structure and list of positions and persons responsible for conducting actions to combat hazards and pollution

11.1. Construction and decommissioning phase decommissioning

Control over the proper conduct of construction/ decommissioning of the OWF is exercised by the Contract Engineer, to whom all information in this regard flows.

Depending on the incoming information, the Contract Engineer will decide on ways to proceed, consisting of, among other things:

- to report a collision or potential collision between two vessels or a vessel and an OWF facility;
- to inform about marine pollution and determine its type and magnitude;
- to take measures to eliminate pollution of the marine environment.

The Contract Engineer supervises subcontractors and has information about the vessels involved and the type and amount of substances on board that may cause pollution of the marine environment.

The Contract Engineer, in consultation with the Investor's representative for environmental protection, is responsible for implementing measures appropriate to the situation and the extent of pollution, and informing the relevant services.

In the event of first-degree pollution, the Contract Engineer, in consultation with the Investor's representative for environmental protection, shall inform the Director of the Maritime Office in Gdynia of the incident and carry out an action to eliminate the pollution with his own resources.

In the event of 2nd and 3rd degree pollution, the Contract Engineer, in consultation with the Investor's environmental representative, shall inform the Director of the Maritime Office in Gdynia of the incident, who shall take control of the conduct of the action.

The director of the Maritime Office in Gdynia supervises the pollution elimination action and, if necessary, orders the SAR service or another specialized organizational unit to carry out the action to combat hazards and pollution.

The SAR service takes charge of the pollution elimination action and undertakes rescue operations with its own resources and, if necessary, cooperates in this regard with the relevant services (State Fire Service, Police, Border Guard, port fire departments) and/or specialized companies.

Third parties

When drifting oil reaches the area of neighboring installations (e.g., other offshore wind farms), third-party hazard and pollution prevention plans may be activated.

On each vessel, in accordance with Regulation 26 of Annex 1 of MARPOL 73/78, there should be, depending on the type of vessel, a Shipboard Oil Pollution Emergency Plan - OPZRO (SOPEP) or Simplified Oil Spill Prevention Plan - UPZRO, approved by the administration of the flag state or other authorized institution and written in the language used by the master and officers of the vessel.

A vessel involved in the construction/ decommissioning of an OWF, if found to be contaminated, should report the information about the contamination to the Director of the Maritime Office in Gdynia and the Contract Engineer and implement its own ship plan. The ship's captain shall take measures to stop or reduce the impact of the harmful substance and prevent the spread of the pollution.

In the case of 2nd and 3rd degree pollution, the Director of the Maritime Office in Gdynia decides to implement the National Plan for Combating Hazards and Pollution of the Marine Environment.

In actions involving international forces, the Helsinki Commission's guidelines for cooperation in combating marine pollution are applied.

The costs associated with the action to remove hazards and pollution are borne by the polluter, in accordance with the "polluter pays" principle. The investigation of marine pollution is carried out by the Director of the Maritime Office in Gdynia, in accordance with the Law of March 16, 1995 on the Prevention of Marine Pollution from Ships (i.e: OJ 2020, item 1955).

11.2. Stage operation

Control over the proper operation of equipment and installations is exercised by the OWF Operations Center located on land (the preliminary locations of the operating ports are: Kolobrzeg, Darlowo, Ustka, Wladyslawowo, Gdynia and Gdansk), to which all information from the technological monitoring of the farm flows.

Depending on the incoming information, the IMF Operations Center Manager will decide on ways to proceed, consisting of, among other things:

- on shutting down or changing the operating parameters of a turbine or other device,
- informed of the need for inspection or repair,
- informing of a collision or potential collision of a vessel with an OWF facility,
- to inform about marine pollution and determine its type and magnitude,
- to take measures to eliminate pollution of the marine environment.

The head of the OWF Operations Center also supervises contractors for periodic inspections and repairs of OWF facilities and has information about the vessels involved and the type and amount of substances on board that could cause pollution of the marine environment.

The head of the IMF Operations Center, in consultation with the Investor's representative for environmental protection, is responsible for implementing actions appropriate to the situation and the extent of pollution and informing the relevant services.

In the event of first-degree pollution, the Manager of the OWF Operations Center, in consultation with the Investor's representative for environmental protection, shall inform the Director of the Maritime Office in Gdynia of the incident and carry out an action to eliminate the pollution with his own resources.

In the case of the occurrence of pollution of the second and third degree, the Manager of the OWF Operations Center, in consultation with the Investor's representative for environmental protection, informs the Director of the Maritime Office in Gdynia about the incident, who takes control of the conduct of the action.

The director of the Maritime Office in Gdynia supervises the pollution elimination action and, if necessary, orders the SAR service or another specialized organizational unit to carry out the action to combat hazards and pollution.

The SAR service takes charge of the pollution elimination action and undertakes rescue operations with its own resources and, if necessary, cooperates in this regard with the relevant services (State Fire Service, Police, Border Guard, port fire departments) and/or specialized companies.

Third parties

When drifting oil reaches the area of neighboring installations (e.g., other offshore wind farms), third-party hazard and pollution prevention plans may be activated.

On each vessel, in accordance with Regulation 26 of Annex 1 of MARPOL 73/78, there should be, depending on the type of vessel, a Shipboard Oil Pollution Emergency Plan - OPZRO (SOPEP) or Simplified Oil Spill Prevention Plan - UPZRO, approved by the administration of the flag state or other authorized institution and written in the language used by the master and officers of the vessel.

The vessel providing services to the Investor in the event of pollution should report the pollution information to the Director of the Maritime Office in Gdynia and the Manager of the OWF Operations Center and implement its own ship plan. The ship's captain shall take measures to stop or reduce the impact of the harmful substance and prevent the spread of the pollution.

In the case of 2nd and 3rd degree pollution, the Director of the Maritime Office in Gdynia decides to implement the National Plan for Combating Hazards and Pollution of the Marine Environment.

In actions involving international forces, the Helsinki Commission's guidelines for cooperation in combating marine pollution are applied.

The costs associated with the action to remove hazards and pollution are borne by the polluter, in accordance with the "polluter pays" principle. The investigation of marine pollution is carried out by the Director of the Maritime Office in Gdynia, in accordance with the Law on Prevention of Pollution from Ships of October 16, 2019.

12. List and deployment of forces and resources to be used in the action to combat threats and pollution

The following is a list of the forces and resources of the various entities and services that may be involved in the rescue operation. The proposed status for the OWF and the current status (as of the date of the study) for the other services are given. During the implementation/liquidation of the IMF, it may change to more modern units.

12.1. Engineer Contract

Equipment of the surveillance ship of the construction/ decommissioning area:

- lightweight flexible (segmented) dam with a total length of min. 200 m,
- absorbent barrier of sorption sleeves (segmented) with a total length of min. 200 m,
- a small device for collecting dirt from the water surface (such as a skimmer or other mechanical collector),
- floating flexible dirt tank(s) with a total capacity of about 20 m3 (only if the ship does not have its own dirt tanks),
- bags for used desiccant sleeves.

12.2. Maritime Search and Rescue Service Rescue

According to the state of affairs as of the date of the study's execution, oil spill fighting vessels at sea equipped by the MSPiR include the M/S Kapitan Poinc and the M/S Czeslaw II. The purpose of the **M/S Captain Poinc** Maritime Multipurpose Rescue Ship is:

- oil pollution control,
- saving lives at sea,
- rescue towing,
- fighting fires on ships,
- contamination recognition,
- underwater work.

The basic technical parameters of the M/S Captain Poinc are shown in the table below:

Table 9. Basic technical parameters of the M/S Kapitan Poinc Marine Multipurpose Rescue Ship

Parameter	Size
Length	49,8 m
Width	13,6 m
Immersion	4,6 m
Power	2 x 1,920 kW
Maximum speed	13 knots
Crew	11 people
Ability to pick up survivors	272 people
Icebreaking Class:	L1

Source: www.shipspotting.com

The equipment of the M/S Captain Poinc consists of the following:

1) Combating oil pollution:
    a) lAMOR active brush system for removing oil contaminants from the water surface (collection width 45 m, max capacity: 2 x 140$^{m3/h}$, storage capacity of collected oil: 512^{m3}),
    b) rO-BOOM 1500 oil dams: 900 m and EXPANDI 4300: 90 m),
    c) oil collectors (TERMINATOR, capacity max: 100$^{m3/h}$, SCANTRAWL A heavy oil collection trawl: 20 m),
    d) a portable tank with a capacity of 5^{m3},

e) workboat;

2) Saving lives at sea:

a) rIB rescue boat (R-11);

3) Fighting fires on ships:

a) pumps: 2 x 1,500 m3/h,

b) water monitors: 2 x 1,200$^{m3/h}$,

c) water and foam monitor: 1 x 250$^{m3/h}$,

d) self-spray system: 2 x 300$^{m3/h}$;

4) Stationary explosive gas detection system (H_2S, NH_3, CO, O_2);

5) Remotely Operated Underwater Vehicle (ROV):

a) search for sunken objects (to a depth of 300 m),

b) condition surveys of underwater objects,

c) wreck research,

d) bottom tests for laying cables and pipelines,

e) lifting objects weighing up to 5 kg from the bottom,

f) registration of underwater images;

6) Other equipment:

a) equipment for emergency unloading of tankers (oils, chemicals),

b) hydraulic crane - max lifting capacity 160 kN, max height 13 m,

c) diving equipment for one team,

d) pSP R-1 emergency medical kit.

The M/S Czeslaw II Marine Oil Pollution Rescue Ship is used to combat oil pollution in port and coastal waters (up to 20 Mm).

Table 10. Basic technical parameters of the M/S Czeslaw II Marine Multipurpose Rescue Ship

Parameter	Size
Length	21,9 m
Width	6,0 m
Immersion	2,36 m
Power	2 x 120 kW

Maximum speed	9 knots
Crew	5 people

Source: www.shipspotting.com

The M/S Czeslaw II's oil pollution control equipment consists of:

a) lAMOR active brush system for removing oil contaminants from the water surface (collection width: 18 m, max capacity: 2 x 20$^{m3/h}$, storage capacity of collected oil: 20^{m3}),

b) oil dams (EXPANDI 4300: 340 m),

c) oil collectors (KOMARA 12k - oil filter, max capacity: 12$^{m3/h}$),

d) dispersant system (VICOSPRAY 1000, capacity: 4.2$^{m3/h}$),

e) a portable tank with a capacity of 5^{m3},

f) pSP R-1 emergency medical kit.

12.3. Maritime Office in Gdynia

According to the status as of the date of the study, the oil spill fighting units at sea, which are equipped by the Maritime Office in Gdynia, include the**oil pollution ship S/v Zodiak**.

The basic technical parameters of S/v Zodiak are shown in the table below.

Table 11. Basic technical parameters of the oil pollution ship S/v Zodiak.

Parameter	Size
Length	61,3 m
Width	10,8 m
Immersion	3,5 m
Power	2 x 960 kW
Maximum speed	13 knots
Crew	12 people

Source: www.umgdy.gov.pl

S/v Zodiac is equipped with an active LAMOR brush system for removing oil contaminants from the water surface (max capacity: 2 x 80$^{m3/h}$, storage capacity of collected oil: 72^{m3}).

13. Procedures for reporting incidents causing danger or pollution to the pollution of the marine environment

All marine pollution must be reported, such as:

- oil spills, including unidentified ones - flowing into the area of the OWF basin,
- visible oil sheen on the sea surface,
- chemical spills, including: de-icers, corrosion inhibitors, mortars, plasticizers, etc.

Notification should be made immediately to the Contract Engineer. It should include basic information on:

- location of the incident,
- the nature of the incident (type and source of pollution and its estimated size),
- time of the event,
- polluters,
- personal and contact information of the reporting person.

Notification must be made without fail even if all the necessary information is not available. They will be supplemented gradually at a later stage.

The degree of pollution (I-III) is determined by the Contract Engineer, in consultation with the Investor's environmental representative, on the basis of the pollution report and, depending on this, triggers information procedures. If there is any doubt about the classification of the contamination, it is better to classify it as a higher degree and possibly downgrade it at a later stage after obtaining the necessary information.

14. Description of how to deal with pollutants collected in the cleanup action waters

Substance-soaked sorbents, packed in polypropylene bags or metal containers, will be transported ashore and taken away - by prior arrangement - to a disposal facility with the appropriate permits (e.g. Port Service S.A. in Gdansk, which has an incinerator for this type of waste).

The collected water-oil mixture will be handed over to a specialized company for the recovery of this type of waste. There are a number of waste disposal companies of this type in the Tri-City area, the most important of which include CTL Północ Sp. z o.o. (Gdynia), Port Service S.A. (Gdansk), Comal sp. z o.o. (Gdansk), Oiler S.A. (Tczew).

All waste generated from marine debris removal will be properly collected and transferred only to companies with legally required permits.

15. Training and exercise plans exercises

The developer should provide for conducting training and exercises related to issues of responding to unplanned events. It should be both theoretical, verifying communication procedures, and practical, using personnel and equipment.
Training should specifically address:

1) the effectiveness of procedures for responding to hazards and identified contaminants,

2) how to alert the various services and cells responsible for combating pollution,

3) the functioning of communications between the various services and cells,

4) notification and elimination of the 1st degree oil spill in the area of the OWF basin.

16. Literature and other sources

16.1. Acts legislation

1. Act of March 21, 1991 on maritime areas of the Republic of Poland and maritime administration (consolidated text Dz. U. of 2022, item 457).
2. Act of October 3, 2008 on providing information on the environment and its protection, public participation in environmental protection and environmental impact assessments (consolidated text Journal of Laws of 2021, item 2373, as amended)
3. Ordinance of the Council of Ministers of September 10, 2019 on projects that may significantly affect the environment (Journal of Laws 2019, item 1839)
4. Ordinance of the Council of Ministers of August 8, 2017 on the manner of organization of combating hazards and pollution at sea (unified text OJ 2022, item 216)
5. Ordinance of the Minister of Family, Labor and Social Policy dated June 12, 2018 on the maximum permissible concentrations and intensities of factors harmful to health in the work environment (Journal of Laws of 2018, item 1286, as amended)
6. International Convention for the Prevention of Pollution from Ships, 1973, done at London on November 2, 1973, as amended by the Supplementary Protocol done at London on February 17, 1978. (Journal of Laws of 1987, No. 17, item 101) and the Supplementary Protocol drawn up in London on September 26, 1997. (Journal of Laws of 2005 No. 202, item 1679) (MARPOL Convention)
7. Council Directive of June 27, 1967 on the approximation of laws, regulations and administrative provisions relating to the classification, packaging and labeling of dangerous substances 67/548/EEC

EIA Act	Act of October 3, 2008 *on access to information on the environment and its protection, public participation in environmental protection and on environmental impact assessments* (consolidated text, Journal of Laws of 2022, item 1029)

1. Introduction

This section presents emissions and disturbances that may provide cumulative impacts in the marine environment as well as existing and designed projects that may be a source of such emissions, thus strengthening the impacts of the BIII OWF. The subject of the environmental impact assessment conducted is the proposed modification of the Project in the parameters approved by the Environmental Decision; however, taking into account the nature of cumulative impacts, the mere change of the Project parameters, if it does not lead to a change in the nature of impacts, will also not result in a change in the scope of projects which should be the subject of the assessment of cumulative impacts. However, since the development of the Report 2015 and the issuance of the Environmental Decision, knowledge on the marine environment of the Baltic Sea has increased, and there have been changes in the investment environment of the Project caused, among others, by the administrative decision, including those related to the issued decisions on environmental conditions, which have been made in the meantime. Therefore, Section 12 Cumulative Impacts from the Environmental Impact Assessment Report Volume II, SMDI Doradztwo Inwestycyjne Sp. z o.o., April 2015, was the starting point for the preparation of this chapter; however, it takes into account the changes in the actual and legal status that occurred in the investment environment of the Project.

At this point, it is also necessary to emphasize the specificity of cumulative impact analyses and the impact of the sequence of events on the effects of the analyses conducted. Taking into account both the methodology of conducting the environmental impact assessment and the applicable regulations, the environmental impact report must include the assessment of cumulative impacts of the project for which the decision on environmental conditions was issued. Thus, each subsequent project during the process of issuing the decision on environmental conditions must take into account the existing projects and the projects for which the decision on environmental conditions was issued. As a consequence, if the already issued decision on environmental conditions are amended (unless it leads to changes resulting in an increase in the scope of impacts) or another environmental impact assessment is performed, in principle, the accumulation should be limited to projects that existed or for which a decision on environmental conditions had been issued prior to issuing a decision for the project for which the procedure of amending the decision on environmental conditions or another environmental impact assessment is performed. Otherwise, the projects for which the decision on environmental conditions was issued after the decision on environmental conditions was issued for the project for which the procedure related to another assessment or amendment to the decision on environmental conditions is conducted could lead to changes in the conditions of the project implementation, and thus to a limitation of the rights acquired.

Regardless of the above-mentioned reservations, this Report, when analyzing cumulative impacts, also took into account those projects for which the decision on environmental conditions was issued after issuing the Environmental Decision and those for which the procedures on the decision on environmental conditions are in progress.

At the same time, it should be noted that in the case of proposed modifications of the parameters of the Project implementation and operation, a significant part of its parameters is reduced, a part remains unchanged in relation to the parameters approved by the Environmental Decision, and the only parameters concerning the total height of the wind turbines and the rotor diameter are increased, which, however; is repeatedly compensated by a radical reduction in the number of wind turbines, and thus the Project, after the modification, does not become a source of impacts or disturbances that could be greater than in the case of the impacts of the Project with the parameters approved by the Environmental Decision. In particular, it should be noted that in the case of updating the parameters of the Project being the subject of this Report, the number of foundations to be constructed will be approx. 70% less than foreseen in the WCS 2015 and twice less than specified in the Environmental Decision, the use of gravity-base foundations under wind turbines was also ruled out, which involves a correspondingly smaller scope and range of impacts related to interference with the seabed and dispersion of sediments at the construction stage and occupation of the seabed at the operation stage, and thus a lower ability to accumulate with impacts of other facilities.

This chapter contains basic assumptions for the analysis of cumulative impacts, which was carried out separately for each element of the environment, in individual Sections of Volume IV of the Report.

2. Emission types and their sources that may cause cumulative impacts

Emissions and disturbances that may cause the impact of the BIII OWF on the environment and their sources are presented in Section 7 of Volume II “Matrix of the project emission-impact interconnections” in Table 1 and described in Sections 4–6 of Volume II of the Report.

The table below presents emissions and disturbances and their sources that may be subject to reinforcement in the case of parallel implementation of other projects typical for the maritime space and specifies the zones in which interaction of impacts may occur.

Table 1. Emissions, their sources and impact accumulation zones

Type of emission or disturbance	Emission source	Type of impacts	Type of project	Accumulation zone
Extraction/change of sediment structure	• Preparation of the seabed for installation of the foundation, cables, pipelines	• Destruction and change of living conditions of benthic habitats • Reduction in population size	• OWF • Cables • Oil&gas	Project area and direct vicinity

Type of emission or disturbance	Emission source	Type of impacts	Type of project	Accumulation zone
	• Geotechnical drilling	• Reduction in feeding grounds		
Increased concentration of suspended matter in water	• Preparation of the seabed for installation of the foundation, cables, pipelines • Installation of the foundations • Laying of cables/pipelines	• Change in living conditions	• OWF • Oil&gas • Transmission infrastructure	Several kilometers around the project area
Redistribution of pollutants deposited in sediments	• Preparation of the seabed for installation of the foundation, cables, pipelines • Installation of the foundations • Laying of cables/pipelines • Heat emission from cables/pipelines	• Change in living conditions • Decrease in population size • Increase in concentration of pollutants in fish of commercial species	• OWF • Oil&gas • Transmission infrastructure	Project area and direct vicinity
Sedimentation of disturbed sediment	• Preparation of the seabed for installation of the foundation, cables, pipelines • Installation of the foundations • Laying of cables	• Change of living conditions of benthic organisms • Change of sediment structure	• OWF • Oil&gas • Transmission infrastructure	Several kilometers around the project area
“Artificial reef” effect	• Foundations installed	• Creation of new habitats • Change in	• OWF • Oil&gas	Project area

Type of emission or disturbance	Emission source	Type of impacts	Type of project	Accumulation zone
		species composition • Increase in food base • Change in living conditions		
Emission of underwater noise (construction stage)	• Installation of foundations • Laying of cables • Vessel traffic	• Behavioral reaction • Temporary threshold shift (“TTS”) • Permanent threshold shift (“PTS”) • Bodily injury • Mortality • Reduction in catches	• OWF • Oil&gas • Transmission infrastructure	Behavioral reaction up to 130 kilometers around the project in the case of piling of 1 foundation without mitigation measures. Up to 60 km with the use of mitigation measures. Up to several dozen kilometers for other activities.
Changes in the regime of sea currents and waving	• Foundations	• Scouring	• OWF • Oil&gas • Transmission infrastructure	Project area
Heat emission from cables / temperature rise	• Cables/pipelines	• Changes in the oxidation and reduction potential • Changes in microbiological activity of sediments • Appearance of alien species	• OWF • Transmission infrastructure • Pipelines	At the project site
Emergence of new structures under the sea surface	• Foundations • Pipelines	• Barrier effect • Change in living conditions • Obstructions to	• OWF • Oil&gas • Transmission	At the project site and its direct vicinity

Type of emission or disturbance	Emission source	Type of impacts	Type of project	Accumulation zone
		shipping and navigation	infrastructure	
Emission of electromagnetic field and radiation	• Cables	• Disturbed orientation • Changes in the use of space • Interference with radar systems • Disturbance to shipping and navigation	• OWF • Transmission infrastructure	At the project site
Emergence of new structures above sea level	• Rotor • Tower • Transformer stations	• Barrier effect • Displacement from habitats • Mortality • due to collisions • Landscape changes • Obstructions to shipping and navigation	• OWF • Oil&gas	Within the project area and within a radius of up to several dozen kilometers around the project area
Emission of surface noise	• Rotor • Vessel traffic • Transformer stations	• Scaring • Displacement from habitats	• OWF • Oil&gas • Substations	Within the project area
Emission of air pollutants	• Vessels • Helicopters	• Deterioration of living conditions for animals	• OWF • Oil/gas • Transmission infrastructure • Navigation	Within the project area
Emission of water pollutants	• Vessels • Leakages from vessels and pipelines • Corrosion protection	• Deterioration of living conditions • Water quality change	• OWF • Oil&gas • Transmission infrastructure • Navigation	In the project area and up to several dozen kilometers around the project area

Type of emission or disturbance	Emission source	Type of impacts	Type of project	Accumulation zone
	• Pointing • Agents to prevent fouling of offshore structures			
Accidental release of waste into water	• Construction process • Construction and service vessels • Construction and service support	• Deterioration of living conditions	• OWF • Oil&gas • Transmission infrastructure • Navigation	Within the project area

Source: provided by the Employer

As can be seen from the list presented in Table 1, the largest zone of potential accumulation of impacts is the underwater noise emitted during foundation works for the structure, consisting in driving the foundation (monopile) or foundation stabilizing piles (tripod, jacket) into the seabed. Such impacts are typical for the stage of construction of foundations used for the foundation of offshore wind turbines, offshore substations and production platforms. As it results from underwater noise modeling, the results of which are presented in Section 9 of Volume II, the zone of significant noise increase during piling of one foundation (multiple impact of one pile) in the worst case scenario (monopile with a diameter of 10 m) may reach for modeled conditions up to more than 120 kilometers from the noise source. If simultaneous piling in two locations is assumed, the accumulation of noise may take place within a radius of approx. 150 kilometers (without mitigation measures). At the same time, it should be emphasized that the recommendations to the Report 2015 indicate the necessity to apply measures limiting noise emission during piling of foundations with the effectiveness not lower than the air curtain technology, significantly limiting the range of noise impacts – up to 30 km with one foundation and up to 50 km with 2 foundations. Therefore, the accumulation zone between the projects will not exceed 100 km. This means that simultaneous piling of two foundations in two OWF projects, not less than 100 km apart, may result in accumulation of impacts in the scope of increasing the level of underwater noise.

It should be emphasized that a new modeling of noise propagation related to installation of monopile foundations with a diameter of 10 m was performed for the EIA Report in question. With the application/introduction of a damping effect of one bubble curtain and appropriate reduction of SEL and SPL at source, it resulted in a situation where none of the threshold values was exceeded at the boundary of the Słowińska Refuge Natura 2000 site. Based on the directions of noise propagation specified in the modeling for the BIII OWF, as well as the maximum ranges for the monopile with the diameter of 12.5 m (BII OWF), the

noise impact zones on marine mammals (seals and porpoises) and fish occurring in the BIII area, in which bodily injury, temporary threshold shift and behavioral reaction consisting in avoidance may occur, were estimated. Directions and ranges of impacts so determined were subject to comparative verification on the basis of results obtained for the project directly adjacent to BIII – Baltica OWF. The assessment also used the results of modeling of cumulative impacts for the case of parallel piling on BIII OWF and Baltica OWF farms (SMDI 2015a, MIG/MEWO 2017). It should be emphasized that the said modeling was performed assuming similar geological conditions prevailing in the aforementioned areas of individual projects (boulder clays with sand and gravel cover). Model calculations showed that one bubble curtain would be sufficient to achieve the desired results. The hammer energy used of 4,500 kJ can also be seen as the worst case scenario, therefore additional mitigation measures can be achieved by using less hammer energy if possible.

The second type of impacts, which may generate accumulation in a significant zone around the emission source, is the impact of large structures raised above the sea level, especially wind turbines, which may reach the height up to 330 m and rotor diameter up to 260 m in the case of the Baltic Power Offshore Wind Farm. The equipment sizes adopted in the current implementation option for BIII are of the following parameters: height up to 310 m and rotor diameter up to 250 m.

The BIII OWF is closest to the coast, just on the BIII OWF to the north there are two wind farms owned by PGE Baltica and Orsted. For the Baltica 2 and Baltica 3 OWFs, the investor assumed the following maximum parameters: height up to 250 m and rotor diameter up to 220 m.

To the east of the BIII OWF, there will be the Baltic Power OWF whose maximum parameters have already been specified above. Behind the BP OWF to the east, a small farm is planned to be constructed, as it consists only of 41 wind turbines of the C WIND OWF with the following parameters: height up to 330 m and rotor diameter up to 280 m.

Structures of offshore wind turbines, spaced in large spaces, may cause accumulation of impacts on the landscape within a radius of several dozen kilometers (visibility of the OWF in the marine landscape may reach up to 50 km, so the maximum accumulation zone may reach approx. 100 km).

Another type of impacts that may accumulate significantly as a result of implementation of separate projects outside the place of their implementation is sedimentation of sediments disturbed during the construction process. In the conditions of low sea currents of the southern Baltic Sea, as it results from the conducted modeling of dispersion of disturbed sediments (BIII OWF, BII OWF, Baltica OWF, Baltic Power), the zone of propagation of disturbed sediments with a concentration of 4 mg/m^3 does not exceed 5 kilometers, and their re-depositing with the thickness of 1.5 mm reaches 2 km. Therefore, the zone of mutual accumulation from two different projects will not exceed 10 km.

In addition, OWFs may accumulate impacts on birds and bats in the form of a barrier effect and scaring away from habitats. According to the assessment of the impact on birds carried out in Section 5 of Volume IV, the zone of bypassing the OWF by flying birds, depending on the bird species, may reach up to approx. 4 km from the furthest wind turbine. Therefore, the accumulation zone between individual farms may cover up to 8 km. Another impact on birds, which may be reinforced in case of accumulation, is the scaring effect related to

another emission, namely surface noise and movement of rotor blades. It refers to buffer of approx. 2 km around the farm. Therefore, the accumulation zone will be to up to 4 km.

To sum up, it should be stated that the cumulative impact assessment should cover the existing or planned projects located not further than within the radius of approx. 100 km (without mitigation measures) around the borders of the BIII OWF, whereas in subsequent zones the following should be assessed:

- Zone 1 – within a radius of up to 100 km from the borders of the BIII OWF – projects that may cause the accumulation of impacts related to noise emission during piling at the construction phase of the BIII OWF or directly after completion of the foundation phase for the BIII OWF, and thus cause the scaring effect for fish and marine mammals or the barrier effect for these organisms (other offshore wind farms and/or production platforms and/or transformer stations and research stations installed on foundations driven into the seabed);
- Zone 2 – within a radius of up to 100 km from the boundaries of the BIII OWF in a line parallel to the coastline – projects that may cause accumulation of landscape impacts during the entire period of operation of the BIII OWF (other offshore wind farms, drilling rigs, research platforms);
- Zone 3 – within a radius of up to approx. 10 km from the BIII OWF boundaries – projects that may cause accumulation of impacts related to the disturbance of bottom sediments at the stage of construction and decommissioning of the BIII OWF (other wind farms, cables and pipelines laid on the seabed, drilling rigs and production platforms, transformer stations);
- Zone 4 – within a radius of 8 km from the borders of the BIII OWF – projects that may cause a barrier effect for birds and bats and a habitat displacement effect, but also located outside this zone, which may create a continuous spatial obstacle without maintaining migration corridors along the main directions of migration routes with a width of not less than 8 km from the nearest obstacles (other offshore wind farms);
- Zone 5 – within a radius of 4 km around the borders of the BIII OWF – projects that may cause the scaring effect for seabirds during the construction and operation of the OWF;
- Zone 6 – within the boundaries of the BIII OWF and in its immediate vicinity – projects that may cause other local impacts indicated in Table 1 (cables, vessels, drilling rigs).

It should also be emphasized that the accumulation of impacts may cover the impacts caused by various activities carried out as part of the construction, operation or decommissioning of the project itself (the so-called internal accumulation). These may be accumulations related to parallel performance of various activities – e.g. disturbance of sediment resulting from preparatory works for installation of foundations and disturbance of sediments caused by anchoring of vessels performing works in the farm area and/or works related to laying offshore cables in the farm area at the same time. These may also be cumulative impacts related to consecutive activities – e.g. piling of subsequent foundations one after the other or agitation of sediments as a result of preparing the seabed for laying power cables in the area of the offshore wind farm. Due to the crucial importance of internal

accumulation for the final results of the assessment of the impact of the entire farm, it will be considered each time when discussing individual impacts of the BIII OWF.

3. Projects in the zone of accumulation of impacts of the BIII OWF

In accordance with the applicable law, the cumulative impact assessment should be carried out taking into account the projects for which the decisions on environmental conditions were issued (Article 66 section 1 point 3b of the EIA Act). However, according to Article 62 section 2 of the EIA Act, there is an obligation to assess the cumulative impact on Natura 2000 sites of all implemented, completed or planned projects regardless of the decisions held by these projects, including those on environmental conditions. Applying the precautionary principle, it is necessary to assess the impact on Natura 2000 sites of all OWF projects known at this stage, which are likely to be implemented, i.e. in relation to the OWFs with at least location decisions and connection conditions.

The designed BIII OWF will be located in the southern part of the Baltic Sea, in the Polish Exclusive Economic Zone, approximately 23 km north of the coastline, at the level of the municipality of Smołdzino and the urban municipality of Łeba (Pomeranian Voivodship).

In the Polish maritime areas, there is a small number of functioning projects that may cause accumulation of impacts with the BIII OWF. However, in recent years, several new projects planned for implementation have been revealed, many of which are located in zones of potential accumulation of impacts of the BIII OWF. Locations of such projects, existing or for which at least some location decisions have been issued or procedures for issuing the decision on environmental conditions have been initiated, are presented in the map below.

The following projects were considered as projects that could cause cumulative impact with the BIII OWF:

- existing or planned projects (holding decisions on environmental conditions), located in individual accumulation zones and which may cause impacts for which a given accumulation zone was determined, in the same or directly following period

as the BIII OWF;

- existing or planned projects for which basic technical parameters have been determined and are publicly available, located in individual accumulation zones and which may cause significant impacts on the integrity, coherence, subject of protection of Natura 2000 sites, in the same or directly following period as the BIII OWF.

The assessment did not take into account unplanned events, as the probability of their occurrence at the same time in two different projects is negligible. The table below presents projects and types of accumulation.

Taking into account the above conditions of the accumulation of impacts, the following were considered as projects that could cause the cumulative impact:

Table 2. Projects that could cause cumulative impact with the BIII OWF

Zone	Projects	Types of accumulation	Notes
Zone 1 – 100 km	Baltica 2 OWF and Baltica 3 OWF, Baltyk II OWF, Baltic Power OWF, FEW Baltic II OWF, BC-Wind OWF, BIII OTI.	Underwater noise during foundation piling (scaring, damage to fish organism and marine mammals). Construction stage. Possible impact on Natura 2000 sites for porpoise and gray seal	The foundation piling on the BIII OWF may be carried out in 2024–2027. During this period, Baltica 2 OWF, Baltica 3 OWF and BP OWF may also be constructed, which have a signed connection agreement with a completion date similar to the BIII OWF. The Investor is not planning to construct the BIII OWF and the Bałtyk II OWF at the same time. Baltica wind farms will be constructed gradually, first Baltica 2 will be constructed and then Baltica 3.
Zone 2 – 100 km	Baltica 2 OWF and Baltica 3 OWF, Baltic Power OWF, Bałtyk II OWF, FEW Baltic II OWF, BC-Wind OWF, BIII OTI	Impact on landscape. Operation stage. No impact on Natura 2000 sites	Currently, the decision on environmental conditions is held by the Baltica OWF projects (Baltica 2 and Baltica 3) and the BIII OWF, Bałtyk II OWF, Baltic Power OWF, FEW Baltic II. C-Wind holds an application for the EIA decision. The accumulation of landscape impacts from the land may be caused by those projects which are located at a distance of up to 50 km from the shore.
Zone 3 – 40 km	Baltica 2 OWF and Baltica 3 OWF, BIII OTI, FEW Baltic II OWF, Baltic Power OWF	Disturbance of bottom sediments at the construction/decommissioning stage “artificial reef” effect at the operation stage	The first stage of construction of the BIII OWF may be carried out in 2024–2027. At these dates, Baltica 2 OWF, Baltica 3 OWF and BIII OTI may be constructed.

Zone	Projects	Types of accumulation	Notes
Zone 4 – 30 km	Baltica 2 OWF and Baltica 3 OWF, BIII OTI, FEW Baltic II OWF, Baltic Power OWF, maritime navigation routes, including: planned deep-water route D, Słupsk Bank TSS and customary navigation route between Lubeck and Venspils	Leakages of oil derivative products	The risk of accumulation of impacts potentially applies to each construction stage of the indicated projects and results mainly from the risk of collision (vessel-to-vessel or vessel-to-structure at sea). In all these projects, service and maintenance activities will be carried out that require vessel traffic.
Zone 5 – 8 km	Baltica OWF (Baltica 2 and Baltica 3), BIII OTI, Baltic Power OWF	Barrier for migratory birds. Scaring away birds from habitats. All stages. Possible impact on Natura 2000 sites.	The main migration routes of birds run in SW-NE directions. Across these directions, during the operation period of the BIII OWF, there may also be a Baltic Power OWF located directly in the vicinity of the Baltica 3 and 2 OWFs; however, the planned area for the development of these OWFs leaves over 23 km of undeveloped maritime area along the coast from the south, where the main migration corridor runs, and over 30 km of the corridor from the north, between subsequent OWF projects prepared on the southern slope of the South Middle Bank. This causes that the cumulative effect of the barrier for birds migrating from Eurasian areas to areas from western and western-southern Europe will not be significant. Moreover, between Baltica 2 OWF (from the west) and the Baltica 3 OWF and BIII OWF there will be an approx. 5 km spacing (corridor) from north to south, which may act as a bird migration corridor. In relation to birds wintering in the areas of the southern Baltic Sea, such as the Słupsk Bank, the Oder Bank or the coastal strip of the Polish maritime areas, an uninterrupted

Zone	Projects	Types of accumulation	Notes
			sequence of 4–6 projects on the north-eastern slope of the Słupsk Bank may constitute a barrier for populations migrating to and from these overwintering areas.
Zone 6 – 4 km	Baltica OWF (Baltica 2 and Baltica 3), Bałtyk II OWF, BIII OTI, Baltic Power	Scaring away from habitats	The cumulative scaring effect for seabirds may theoretically concern OWF projects located directly in the vicinity of the BIII OWF – Baltica OWF (Baltica 2) and FEW Baltic II. This effect will mainly concern displacement of wintering bird populations occurring in the Słupsk Bank area and its direct vicinity. Theoretically, FEW Baltic II project is within such a designated range, however, due to its distance from the Słupsk Bank, its significance will be negligible. Scaring at the construction stage may accumulate with the Baltica OWF (Baltica 2 and 3), as these projects may be constructed in parallel or immediately one after the other with the BIII OWF.
Zone 7 – farm area	BIII OWF,	• Increased concentration of suspended matter in water, • Redistribution of pollutants deposited in sediments, • Increase in sediment and water temperature, • Emission of electromagnetic field and radiation.	Laying export cables in the BIII OWF area may result in accumulation of impacts with those caused by installation works at the farm. At the operation stage, impacts caused by internal cables of the farm and connection infrastructure may accumulate.

Unlike in the Report 2015 and due to the expiry of licenses for exploration and prospecting in the Baltic Sea and licenses for oil and gas extraction from the B3, B4, B6 and B8 fields (and non-issuance of new licenses in the areas in question or in other areas relevant for the cumulative impacts of the BIII OWF), no cumulative impacts with this projects have been accounted for.

Based on the above analysis, it should be stated that the projects that may actually cause the accumulation of impacts with the BIII OWF at the construction/decommissioning and operation stages, respectively, may be the projects indicated in the table below.

Table 3. Projects that may actually cause accumulation of impacts with the BIII OWF at the construction or operation stage

Project	Types of cumulative impacts at the construction/decommissioning stage	Type of cumulative impacts at the operation stage
Baltica OWF (Baltica 3)	• Underwater noise • Bird scaring • Disturbance of bottom sediments at the construction/decommissioning stage • Leakages of oil derivative products	• Disruption of the landscape, • Leakages of oil derivative products • Barrier for migratory birds • “Artificial reef” effect • Scaring effect
Baltica OWF (Baltica 2)	• Underwater noise • Bird scaring • Disturbance of bottom sediments at the construction/decommissioning stage • Leakages of oil derivative products	• Disruption of the landscape • Leakages of oil derivative products • Barrier for migratory birds • Scaring effect • “Artificial reef” effect
Bałtyk II OWF	• It is assumed that the project will not be built in parallel with the BIII OWF, so accumulation will not occur at this stage	• Disruption of the landscape • Barrier for migratory birds • Leakages of oil derivative products • Scaring effect
FEW Baltic II	• No impacts due to divergent	• Disruption of the landscape

	construction dates	• Leakages of oil derivative products • Barrier for migratory birds • Scaring effect
Baltic Power OWF	• No impacts due to divergent construction dates	• Barrier for migratory birds • Disruption of the landscape
Maritime navigation routes, including: • planned deep water route D, • Słupsk Bank TSS, • customary navigation route between Lubeck and Venspils	• Leakages of oil derivative products	• Leakages of oil derivative products
BIII OTI	• Increased concentration of suspended matter in water, • Redistribution of pollutants deposited in sediments	• Increase in sediment and water temperature • Emission of electromagnetic field and radiation
C-Wind OWF	• The project will not be constructed in parallel or directly after the BIII OWF, so there will be no accumulation at this stage	• Disruption of the landscape

4.1. Offshore wind farms

To assess the cumulative impact of the above-mentioned OWF projects, either available data on parameters were used, on the basis of environmental impact reports and issued environmental decisions – BII OWF, Baltica 2 and 3 OWF, Baltic Power OWF, C-Wind OWF, and FEW Baltic II OWF.

However, it should be emphasized that the decisions on environmental conditions do not directly determine the period of the project implementation, but they have a specific legal date when they may form the basis for applying for subsequent decisions permitting the project implementation. Knowledge of the date of issuing the decision on environmental

conditions and information disclosed by investors on the OWF projects being prepared form the basis for determining the date of implementation of individual projects.

Table 4. Parameters of offshore wind farms that may accumulate impacts with the BIII OWF

Parameters of OWF accumulation	Bałtyk II OWF	Baltica 3 OWF[1]	Baltica 2 OWF[2]	Baltic Power OWF	FEW Baltic II	C-Wind OWF
maximum capacity [MW]	1 200	1045,5	1500	1 200	350	500
number of WTs [pcs]	60	90	119	126	44	41
height [m]	300	250	250	330	300	330

completion date	2025-28	2025-27	2024-26	2024-26	2028-30	2026-2028

4.2. Offshore Transmission Infrastructure

The energy generated by the BIII OWF (and the BII OWF planned to be completed at another date) will be transferred to the shore using export cables. They will not be a part of the farm, but a separate project named Offshore Electricity Transmission Infrastructure ("OTI"), owned by MFW Bałtyk III Sp. z o.o. (formerly Polenergia Bałtyk III), with its registered office in Warsaw.

For the OTI, location permits were issued for laying submarine cables in EEZ and in territorial waters of the Republic of Poland. Moreover, in 2019, the Investor obtained a decision on environmental conditions for this project (RDOŚ-Gd-WOO.4211.12.2016.KSZ/AJ.29). This project is described in Chapter 7 of Section 3 of Volume II of the Report.

[1] The Baltica OWF area covered by the permit for erection and use of artificial islands, structures and devices issued for the Baltica 3 OWF, covered by the joint decision on environmental conditions together with the Baltica 2 area.

1. Introduction

This section of the Report contains the climate characteristics of the Project area along with climate change trends in the Project area. Offshore wind power is a zero-emission technology that generates electricity using a renewable energy source such as wind. The dynamic development of offshore wind energy is related to the climate policy based on renewable energy sources at the EU and national levels. The most important strategic documents whose environmental objectives (including climate) the BIII OWF may affect are presented in Chapter 2 of Volume I of the Report.

An assessment of the Project's climate impact and an assessment of climate impacts on the Project are presented in Volume IV, Chapter 13 of the report.

2. Characteristics

2.1. Conditions climatic

The Baltic Sea is located in a temperate climate zone with high seasonal variability. Air temperature ranges from about -30°C in winter, to 30°C in summer. The average air temperature in the South Baltic coastal zone ranges from 5.3°C in Maarianhamina to 7.9°C in Arkona and Kolobrzeg (Uścinowicz et al. 2011). The average annual wind speed in the Baltic Sea varies between 6-8 m/s, with values lower than 6 m/s measured in the coastal zone, while values higher than 7 m/s in the Baltic Proper. The highest wind speeds, over 8 m/s, were recorded in the Pomeranian Bay (Uścinowicz et al. 2011).

An important indicator is sunshine (the total number of hours during which sunlight falls directly on a specific location) - for the Baltic Sea it is: between 1,592 (Lund) and 1,881 (Visby station). The annual distribution indicates low sunshine in December and January (< 40 hours at all research stations, except Tallinn, where it is < 20 hours) and high sunshine from May to August (> 200 hours per month) (Ushinovich et al. 2011). Cloud cover in the Baltic area is quite high, with an annual average value ranging from 65% (Arkona, Maarianhamina) and 71% (Kolobrzeg). The most cloudy period is autumn and winter from November to February (cloud cover > 70%). Noticeably less cloud cover was observed in May and August, with most stations below 60% or slightly above this value. The number of days with precipitation on the Baltic coast varies from 158 to 182 days. The most frequent rains occur in Klaipeda, Kolobrzeg, Kaliningrad and Tallinn (≥ 180 days). The rainiest months are November, December and January (it rains about 20 days). The rains are rainiest from April to September (less than 15 days) (Uścinowicz et al. 2011).

Ice phenomena in the Baltic Sea occur during each winter, and are characterized by varying intensity in each of the years analyzed. Their duration also varies greatly geographically. In the Baltic Proper, ice phenomena last from 0 to 40 days (Uścinowicz et al. 2011).

In the area of the Polish exclusive economic zone, ice cover in the last 50 years has been rare and short, with an average thickness of less than 30 cm (Schmelzer, Holfort et al. 2012). Analysis of multi-year data shows a significant increase in surface air temperature over the past 140 years. Since 1871, the average annual temperature has shown an increase of 0.11°C per decade north of the 60°N parallel and 0.08°C south of the 60°N parallel, while the global trend was about 0.05°C per decade from 1861 to 2000 (HELCOM 2013). The daily temperature cycle is also changing and there has been an increase in temperature extremes. The above changes are causing changes in the seasons: the length of the

growing season has increased, while the length of the winter season has decreased. Climate change modeling indicates a further increase in temperature in the Baltic Sea area, and this increase will continue to be greater than the corresponding increase in average global temperature. The greatest warming is predicted in the north during the winter season. The increase in winter average daily temperatures will be most pronounced during the coldest periods, while extreme high temperatures will occur more frequently in summer than at present (HELCOM 2013).

The amount of precipitation in the Baltic Sea area has varied regionally and seasonally over the past century, this has included both increases and decreases in precipitation (HELCOM 2013). In the second half of the twentieth century, there was a trend of increasing precipitation in winter and spring. For individual seasons, however, the trends were different. Precipitation has a significant impact on the volume of river runoff, analyses of this runoff, based on data from the past century, have shown that there has been a decline in the annual volumes of water delivered from the southern part of the Baltic Sea basin, indicating that the southern regions of the Baltic Sea basin may become drier with rising air temperatures. In contrast, trends in the north and Gulf of Finland indicate an increase in annual flows at warmer temperatures. In a future warmer climate, extreme precipitation events are expected to be more frequent. Instead, the amount of snowfall in the region may decrease, even significantly for the southern part of the catchment area (HELCOM 2013).

The annual cycle of river runoff will fluctuate considerably. The maxima currently recorded during late spring can occur earlier, even in February or January. These changes will result from rising temperatures and earlier snowmelt, as well as changes in the annual precipitation cycle and increased evaporation (HELCOM 2013).

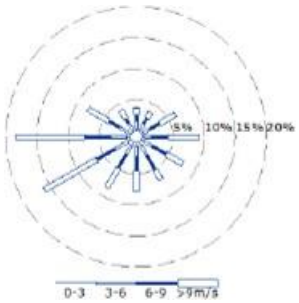
The above climate changes will translate into changes in sea surface temperature. The highest temperature rise may occur in the Gulf of Bothnia and South Bothnia during the summer and in the Gulf of Finland in the spring. The increase in summer sea surface temperature could be about 2°C in the southern parts of the Baltic Sea and about 4°C in the northern parts by the end of this century. The surface water layer is expected to warm more strongly than the bottom layers in all Baltic Sea sub-basins. The above projected changes will have a significant impact on the occurrence of ice events - simulations indicate that there will be a decrease in ice coverage in the future (HELCOM 2013).

As a result of the study of meteorological conditions at the stage of report preparation in 2015 and in 2019[1], it was found that in the area of the location of the planned project, the prevailing winds were from the southwestern and western sectors, with wind speeds above 9m/s.

Wind speeds range from 0-5 degrees on the Beaufort scale. The period when winds of greater strength blow is autumn and winter, which coincides with the period of storms at sea, where wind speeds exceeded 20-23 m/s.

[1] 1. DNV GL, Central Baltic III Wind Farm, Measurement campaign Data - Summary, 2019

Figure 1. Wind speeds and direction over the sea surface in the IMF B III field



Source: 1. DNV GL, Central Baltic III Wind Farm, Measurement campaign Data - Summary, 2019

Air temperature had an annual pattern consistent with the average temperature pattern in the Baltic area (Climate of Baltic Sea Basin, 1998). The minimum value did not exceed -10 o, while the maximum temperature was less than 25o C. The area of open sea blurs the influence of the continent on thermal conditions. Winters are milder and summers are cooler. The possibility of ice phenomena in the area of OWF BIII is described as negligible.

2.2. Greenhouse gas emissions greenhouse gases

Based on the results of the 2019 national greenhouse gas inventory (see Table 1; NOBiZE 2021), which includes carbon dioxide (CO2), methane (CH4), nitrous oxide (N2O), the HFC (hydrofluorocarbon) gas group, the PFC (perfluorocarbon) gas group, sulfur hexafluoride (SF6), and nitrogen trifluoride (NF3), total greenhouse gas emissions at the national level amounted to 412856.37 kt ekw. CO2 (excluding greenhouse gas emissions and removals from category 4. Land Use, Land Use Change and Forestry).

Table 1. National greenhouse gas emissions in the base year and in 2019. (KOBiZE 2021)

Greenhouse gas	Emissions in eq. CO_2 [kt]		(2019-baseline)/baseline [%]
	Base year	2019	
CO_2 - with category 4	450855.61	302484.60	-32.91
CO_2 - without category 4	472043.58	319520.97	-32.31
CH_4- with category 4	73564.91	45301.19	-38.42
$CH_{4\text{-no}}$ category 4	73515.72	45276.30	-38.41
N_2O- with category 4	35512.74	24069.86	-32.22
N_2O- without category 4	33512.00	22101.21	-34.05
HFC	171.97	3744.68	2077.53
PFC	171.97	10.76	-93.74
A mix of HFCs and PFCs	NA,NO	NA,NO	NA,NO
SF_6	29.12	90.75	211.64
NF_3	NA,NO	NA,NO	NA,NO
Total - with category 4	560306.32	375701.84	-32.95
Total - without category 4	579444.36	390744.67	-32.57

[a)] base year is understood in Table 1 and throughout the report as: 1988 for CO_2, CH_4 and N_2O, 1995 for HFCs, PFCs and SF_6, and 2000 for NF_3.

NA - not applicable, NO - not present

Compared to the base year, the volume of emissions for 2019 decreased by 32.6% (KOBiZE 2021). The dominant role in national emissions is played by CO2 (81.8%), the share of methane and nitrous oxide is much smaller, respectively: 11,6% i 5,7%. Fluorinated industrial gases (so-called F-gases) account for a small share of national greenhouse gas emissions (about 1.0% in total), and NF3 emissions have not been recorded in Poland.

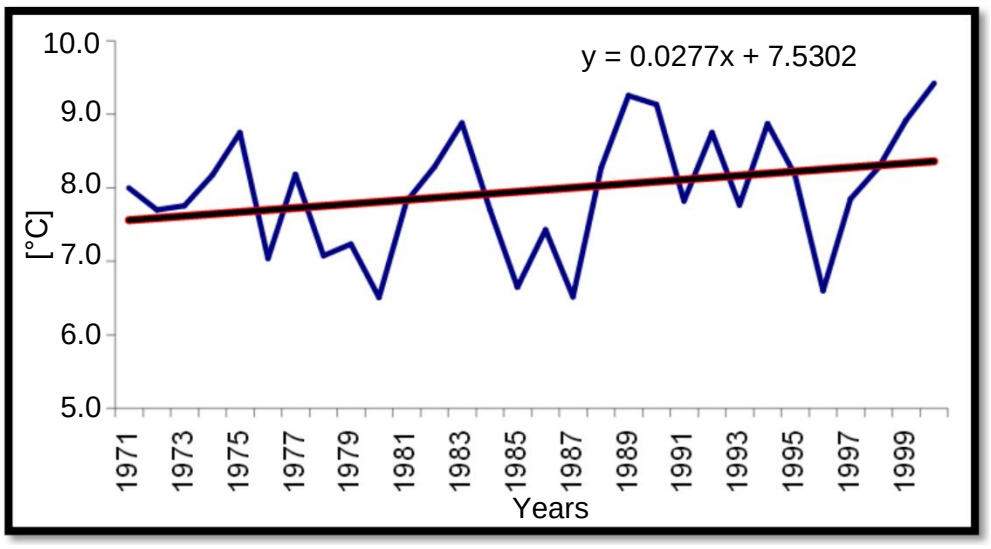
Based on multi-year observations, the course of change in aggregate greenhouse gas emissions replicates the trend in CO2 emissions: there is a noticeable decline in greenhouse gas emissions between 1988 and 1990. This is a result of changes in the domestic economy. The decline in emissions continued until 1994, after which emissions began to rise, reaching a peak in 1996 (economic growth). GHG emissions stabilized between 2008 and 2011 (except for a marked decline in 2009 as a result of the global economic slowdown). The significant increase in greenhouse gas emissions between 2016 and 2018 was influenced by the economic recovery and the increase in fuel consumption in the road transport sector. In 2018-2019, there was a decrease in greenhouse gas emissions, mainly the result of lower consumption of fuels burned in stationary sources, primarily coal and lignite. Emissions also decreased in the agricultural sector due to, among other things, lower (by nearly 16%) use of mineral fertilizers, as well as in the waste sector, where the amount of municipal waste disposed of through landfilling and industrial waste and sewage sludge disposed of thermally decreased. In contrast, 2019 was another year of increased emissions in the road transport sector due to higher fuel consumption than in 2018 (KOBiZE 2021).

2.3. Climate change trends - scenarios

Air temperature and precipitation in climatology are basic elements in describing the characteristics of climate from the global to the local scale. Based on the multi-year course of air temperature, oscillations and trends of temperature over shorter or longer periods are determined, identifying them as "quasi-cycles" of warming or cooling. In rainfall series - dry, wet or normal periods are distinguished.

Based on homogeneous observational material, a 30-year series of air temperature over Poland (1971-2000) was adopted, as shown below.

Figure 2. The course of the average values of air temperature in the territory of Poland in 1971-2000



Source: Zawora T., Ziernicka - Wojtaszek A. 2005. Influence of weather and climate on agrotechnical activities and planning of crops in the area of Poland. Problems of Ecology 5 (53),pp. 269-271

As shown in the figure above it is noticeable:

- high variability in air temperature from year to year;
- steadily increasing temperature trend (y = 0.0277x + 7.5302): the series is brought to the year 2000, the temperature trend obtains a temperature increment value of 0.58°C/100 years;
- significant variability in area average air temperatures over the analyzed period with the highest temperature over the half-century period of 9.4°C falling in the year 2000.

Analysis of the value of the average annual air temperature in the area of Poland in the second half of the 20th century on the basis of the collected data allows us to conclude that there has been a clear warming of the climate.

There has been a change in the structure of precipitation over most of Poland, involving a sharp increase in the number of days with heavy daily precipitation: daily precipitation of ≥10 mm and ≥20 mm increased to 10 days per decade and 4 days per decade , respectively, almost all over Poland; precipitation of ≥30 mm - more than 3 days per decade, except on the coast and in northeastern Poland, precipitation of 50 mm by 2 days per decade - clearly in southern and central Poland and in places in the north.

There was an upward trend in the sum of maximum 5-day precipitation (up to 15 mm/5 days per decade) on the coast (from Szczecin and Swinoujscie to Hel) and in the southern part of Poland, and a decrease in the height of maximum 5-day precipitation running along the belt from Slubice and Gorzow Wlkp, through Suwalszczyzna to the southern part of Podlasie.

The precipitation data for July 2011, in which monthly precipitation totals across the country exceeded precipitation norms by as much as 400%, may serve as a rarity and an event demonstrating the strong dynamics of changes in precipitation patterns. Such a rainy July has not been observed since 1997. At the same time, studies show that the so-called continuous and small precipitation (< 1.0 mm) is disappearing, that the rainless periods (droughts) have lengthened - up to 5 days/decade, while the number of days with precipitation > 10 mm/day has increased.

The greatest impact on climatic conditions is exerted by extreme phenomena, the current increase in the number of occurrences of which is noticeably changing the dynamics of climate features in Poland. Thermal phenomena unfavorable and troublesome for the environment and society include heat waves (sequences of days with maximum daily air temperature ≥30°C lasting for at least 3 days), most often occurring in the southwestern part of Poland and least often in the region of the coast and mountains, with the longest sequences of hot days lasting ≥17 days (Nowy Sącz, Opole, Racibórz).

In most of Poland, there are decreasing trends in the number of frosty and very frosty days (days with daily maximum temperature ≤0°C and days with maximum temperature ≤-10°C, respectively). Slight increases in the number of frosty days were marked only in mountainous areas and the southwestern part of Poland. Over most of the country, the length of frost periods showed a slight upward trend, with the longest lasting more than 20 days and, except in the mountains, occurring only in the northeastern part of the country, while decreases were marked only in coastal areas and in the mountains. The longest periods of very cold weather occurred in the northeastern and eastern parts of the country (10-

20 such episodes in 40 years), while the rest of the country recorded one to several periods of very cold weather - with the exception of coastal areas, where no such temperatures were recorded. In addition, as shown in the figures above, sea level rise is observed for the analyzed location due to tectonic reasons - the phenomenon of post-glacial rebound (post-glacial rebound) and changes in currents will cause a sea level rise of 0.2 to 0.4 meters.

Figure 3. Trends in relative sea level measured for tidal stations from 1970 to 2016

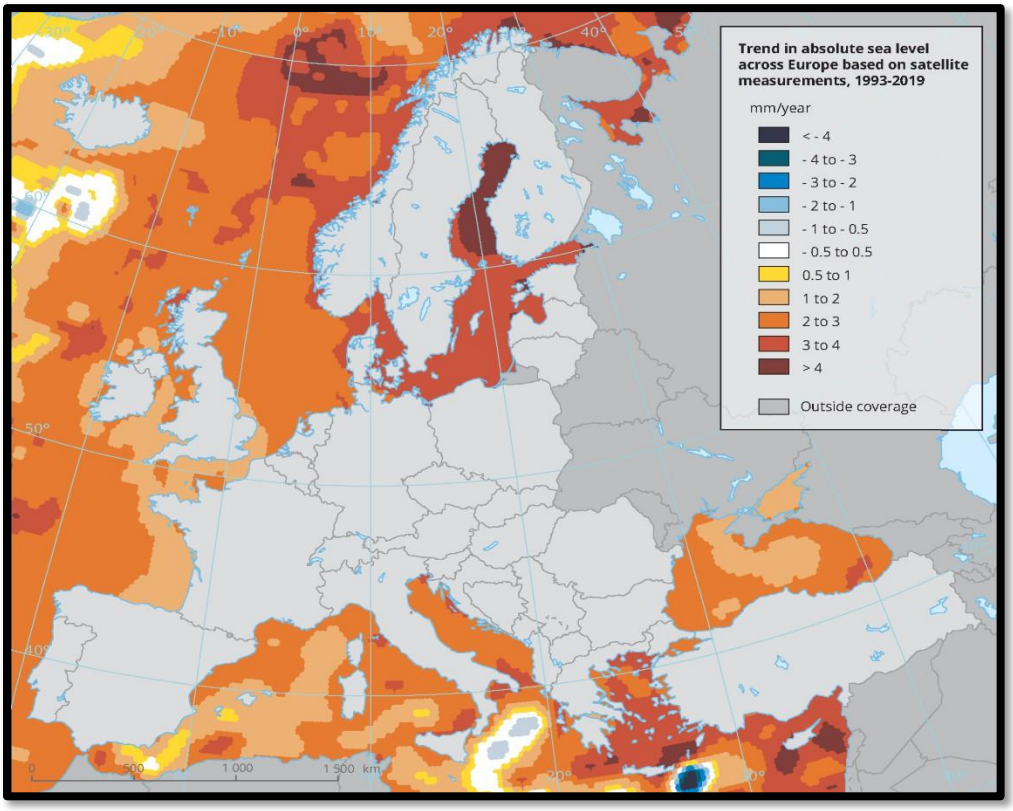
Figure 4. Trend of sea level changes in Europe



Source: https://www.eea.europa.eu/data-and-maps/indicators/sea-level-rise-6/assessment (Access date: 24.03.2022)

Scenarios of climate change in Poland were developed using the best tools of modern climatology - hydrodynamic models of the climate system. These models, constructed according to the degree of knowledge and understanding of the laws of physics, provide a three-dimensional description over time of climate variables. Unfortunately, they are also fraught with many uncertainties due to shortcomings in techniques (knowledge). And therefore, in any consideration of potential scenarios, it is necessary to take into account possible changes in certain ranges. Hence, a bundle of projections, obtained from different regional models, controlled by different boundary conditions generated by general circulation models, is analyzed.

The climate change scenarios for Poland are based on simulations conducted in the EU ENSEMBLES project (http://ensemblesrt3.dmi.dk), which produced the largest set of climate projections currently available for Europe for the 21st century. The results of the ENSEMBLES project make it possible to take into account various possibilities for the development of the climate system, are widely used and form the basis of many studies on climate change in other European countries. To assess climate change in Poland, the results of 8 regional models were used, i.e. RM5.1, DMI-HIRHAM5, MPI-M-REMO, KNMI-RACMO2, SMHIRCS, DMI-HIRHAM5, METO-HC_HadRM3Q0, ETHZ-CLM

with boundary conditions from 4 global models (ARPEGE, ECHAM5, BCM, HadCM3Q0). Projections were made assuming the SRES A1B emissions scenario (Nakicenovic, Swart, 2000). Simulations conducted using this scenario reflect a picture of average changes relative to the extreme scenarios (A2 and B1).

On the other hand, the differences resulting from the use of a bunch of models are very important and it is essential to take them into account.

The 10th and 90th percentiles method was used to analyze temperature changes. A percentile of 10 indicates temperature values below which 10% of all temperature values occur in a given period, while a percentile of 90 cuts off the top 10% of temperature values. As shown in the figure below, the climate model indicates expected warming for both periods and for both seasons, with a clear advantage for the last thirty years given the analysis, which is important for infrastructure investments such as an offshore wind farm, due to its assumed long-term operation.

As can be seen from the figures below, for winter, by far the larger increases should be expected in the low temperature range (percentile 10), strongest in northeastern Poland, up to 2, 5°C in the first period and above 4, 5°C in the second. Increases in high winter temperature values are more homogeneous for the whole country and slightly smaller, about 1.5°C in 2021-2050 and about 3, 5°C in 2071-2100 for the 90th percentile. In summer (b), the increase in low temperatures represented by the percentile 10 reaches about 1°C in 2021-2050 and about 3°C in 2071-2100. There is a greater increase in high temperatures, especially in southeastern Poland, from 2.5°C in the first period studied to more than 4.5°C by the end of the century.

Figure 5. Differences in air temperature percentiles, between the periods 2021-2050 and 2071-2100 and the reference period 1971-2000 (a. winter, b. summer)

The spatial distribution of relative changes in precipitation, as shown in the figure below, indicates an increase in winter precipitation reaching about 15% in the northern part of the country in 2021-2050 and up to more than 20% in the eastern part in 2071-2100. Summer precipitation is expected to decrease by the end of the century, the greatest in the southeast. Spring precipitation in the first period decreases slightly in the western part of the country, while in the second period it is noticeable that it increases by about 10% across the country. For autumn, trends are weakest, only a slight decline can be expected in the northern regions of the country.

The results of the climate scenario analysis show that:

- temperature shows a clear upward trend throughout the country, more warming is expected towards the end of the century, temperature increases are regionally and seasonally differentiated, the largest temperature increase above 4.5°C in the last three decades of the 21st century in the ranges of low temperature values is seen in winter in the northeastern region of the country, and for high temperature values in summer in southeastern Poland;
- the increase in temperature is correctly reflected in the course of all climate indices based on this variable, for example, there is a clear tendency to lengthen the thermal growing season, its earlier onset is noted, the number of days with a minimum temperature less than 0°C is decreasing and the number of days with a maximum temperature higher than 25°C is increasing, of course, the course of the indices is regionally determined, which is very well reflected in the models;
- for precipitation, the trends are less clear, with simulations indicating some increase in winter precipitation and a decrease in summer precipitation by the end of the century;
- temperature characteristics such as the number of days reflect upward trends in temperature change;
- precipitation characteristics show an increase in rain-free periods, an increase in maximum precipitation totals and a reduction in the duration of snow cover (see table below).

Table 2. Scenario of changes of selected climatic characteristics for the area of Poland

	1971-1980	1981-1990	1991-2000	2001-2010	2011-2020	2021-2030	2041-2050	2061-2070	2071-2090

OWF BIII / Project	Bałtyk Środkowy III Offshore Wind Farm
IMF Baltica	Baltica offshore wind farm
Baltic Power OWF	Baltic Power Offshore Wind Farm
Report	The Environmental Impact Assessment Report for the purposes of the procedure finalized by the decision of the Regional Directorate for Environmental Protection dated July 7, 2016, ref. No. RDOŚ-Gd-WOO.4211.12.2015.KP.22
EIA Act	Act of October 3, 2008 on access to information on the environment and its protection, public participation in environmental protection and on environmental impact assessments (consolidated text, Journal of Laws of 2022, item 1029)

1. Introduction

This Volume III of the Report contains a description of the environment in which the Project involving the construction of the offshore wind farm OWF Central Baltic III will be implemented, as well as the environment within the range of its impact. This volume fulfills the requirements of Article 66 (1) (2) and (3) of the EIA, and provides the basis for the environmental impact analyses performed in the next, Volume IV of the Report.

This volume supplements and updates Volume III of the Environmental Impact Report[1], which was the basis for the issuance of the current Environmental Decision[2].

The various sections of this volume are based on the environmental studies carried out in 2012-2014 by the Maritime Institute in Gdansk for the environmental impact assessment for the Central Baltic offshore wind farm III project, and supplemented with more recent data where necessary.

Since the total area of the farm that is the subject of this report, where the construction of the power plant is possible, is slightly smaller and within the boundaries of the area described in the Environmental Impact Report for the Central Baltic III offshore wind farm, prepared in 2015, this report refers to the methodology, scope and results of the previously conducted studies.

In addition, during the work on environmental characterization, the available results of the Baltic Sea environment research conducted within the framework of the State Environmental Monitoring (PMŚ) were used, as well as the results of research conducted for the project of the neighboring BIII offshore wind farm - the 2016- 2017 Baltica offshore wind farm and the 2018-2020 Baltic Power offshore wind farm. The studies for the environmental impact assessment of the aforementioned farms were carried out by an executive team with a similar composition as the studies for OWF BIII, using similar, comparable methods. Parts of the study area overlapped, as there was some overlap between the buffer zones.

In accordance with Article 66 (1) (2) of the EIA Act, the report contains a description of the natural elements of the environment covered by the scope of the anticipated impact of the planned project on the environment, including the elements of the environment protected under the Act of April 16, 2004 on nature protection. In addition, in accordance with Article 66 (1) (3) of the UoA, the report (in the section on archaeological research) shall include a description of existing monuments protected under the regulations on the protection and care of historical monuments in the vicinity or in the immediate range of the impact of the planned project.

The report also included monitoring reports on vessel and fishery traffic in the area of the proposed farm, necessary for a socioeconomic assessment.

OWF BIII / Project	Bałtyk Środkowy III Offshore Wind Farm
IMF Baltica	Baltica offshore wind farm
Report	The Environmental Impact Assessment Report for the purposes of the procedure finalized by the decision of the Regional Directorate for Environmental Protection dated July 7, 2016, ref. No. RDOŚ-Gd-WOO.4211.12.2015.KP.22
RDSM	Directive 2008/56/EC of the European Parliament and of the Council of 17 June 2008 establishing a framework for Community action in the field of marine environmental policy (Official Journal. EU L164, 25.06.2008, pp. 19-40; "Marine Strategy Framework Directive.")

1. Introduction

The section presents a characterization of the hydrological and hydrochemical conditions present in the area of OWF BIII and in the zone of its potential impacts based on the results of hydrological and hydrochemical studies of marine waters. The results of the study, along with a description of the methodology used, are attached as Appendix C to the Report.

Other available materials and information on marine waters were also used for the development of this section.

For the preparation of the Report, including the determination of hydrological and hydrochemical conditions and their sensitivity to impacts from the Project, the results of the following studies were used:

- marine water quality (physical and chemical properties) including: turbidity, salinity, water temperature at the bottom and at depths of 4, 8, 16 m from the surface, oxygen conditions (dissolved oxygen, five-day oxygen demand (BOD5), total organic carbon (TOC), acidity (pH) and alkalinity, nutrients (ammonium nitrogen, nitrate nitrogen, total nitrogen, mineral nitrogen, phosphates, total phosphorus), suspended solids, and the content of substances particularly harmful to the environment, such as: mercury, nickel, lead, cadmium, arsenic, total chromium, chromium (VI), phenols, cyanides, mineral oils, polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), measurements of the activity of radioactive isotopes of cesium (137 Cs) and strontium (90 Sr);
- meteorological indicators including: wind speed and direction, air temperature, atmospheric pressure;
- hydrodynamic processes taking into account: waves on the sea surface (wave heights, periods and propagation directions), water flows throughout the depth profile (flow directions and velocities).

2. Characteristics of hydrological and hydrochemical conditions hydrochemical

Based on the results obtained, the following are the key conclusions of the studies and analyses performed, which may affect the course of the impact assessment. The studies performed are considered sufficient to obtain reliable and representative data for assessing the environmental impact of OWF BIII.

The research methodology and detailed summaries of the various results of the studies performed, along with their analysis, are presented in Appendix C of the Report.

2.1. Water quality marine

Physical and chemical parameters

The physical and chemical parameters of the water in the area of the planned project did not differ significantly from typical values accepted for the waters of the southern Baltic Sea.

These waters are characterized by an alkaline reaction, with a pH in the range of 7.0 - 8.8 (with an average value of 8.12), alkalinity averaging 1.75 $^{mval\text{-}dm\text{-}3}$ (showing no seasonal or depth-related changes), and relatively good oxygenation (concentrations in all measurement periods were in the range >= 6 $^{mg\text{-}dm\text{-}3}$) characterized by seasonal variation, typical of southern Baltic waters. The assessment of water

quality in the BIII OWF area, taking into account the oxygen content of the bottom layer during the summer (VII, IX) indicates a good condition (no oxygen deficit).

Good water quality is also indicated by the results of the BOD5 and OWO tests, which were within the limits for water quality class I throughout the measurement period.

The lowest average concentrations of suspended solids in the study area occurred in autumn and winter, while the highest concentrations occurred in April, which could be due to the start of increased primary production.

Samples taken in October 2012 and February 2013 showed very low concentrations of suspended solids. The average suspended solids content in October was less than 0.5 $^{mg\text{-}dm\text{-}3}$, while seawater samples taken in February showed suspended solids concentrations ranging from less than 0.5 $^{mg\text{-}dm\text{-}3}$ to 0.96 $^{mg\text{-}dm\text{-}3}$. During the spring period, an increase in suspended solids in the water tone was observed. In seawater samples taken in April, the average suspended solids concentration in the study area was 4.48 $^{mg\text{-}dm\text{-}3}$. In the seawater samples taken from July to November 2013, the average suspended solids content remained between 1.83 and 2.53 $^{mg\text{-}dm\text{-}3}$.

The concentrations obtained are typical of Baltic Sea waters during the respective measurement periods.

The content of biogenic substances (total nitrogen, mineral nitrogen (nitrates, nitrites and ammonia), phosphates and total phosphorus) in the studied waters showed seasonal variability characteristic of southern Baltic waters. The lowest concentrations of the substances tested were found in May and July. In contrast, during the winter months (December, February) an increase in content was observed in accordance with the seasonal trend of nutrient recovery.

In the samples from the BIII OWF area, nitrites were found in a small number of water samples taken in February, April and September. In October 2012 and July and November 2013, nitrite concentrations in the study area were below the limit of quantification of 0.2 $^{pmol\text{-}dm\text{-}3}$. The highest levels of nitrite were found in samples taken in September 2013. This is likely the result of an increase in nutrients after a summer phytoplankton bloom. The presence of nitrite was found mainly in the northeastern part of the study area.

Higher nitrate concentrations were found in water samples taken in the fall and winter, which is consistent with the cycle of seasonal nitrate changes in marine waters. During spring and summer, a decrease in nitrate content was observed in the water samples, which is related to the period of increased phytoplankton vegetation and primary production.

Ammonia in waters taken from the BIII offshore wind farm area in October 2012 and February and November 2013 was found in few samples. Higher concentrations of ammonia were found in July, September and November. The concentrations found in the analyzed surface and bottom water samples do not deviate from the concentration values characteristic of Baltic waters. In the bottom layer, the highest concentration of ammonia became apparent during the autumn period (October 2012 and November 2013), when there is a subsidence of organic matter after an intense phytoplankton bloom.

Changes in mineral nitrogen content are consistent with seasonal changes in nutrients observed in Baltic Sea waters. The obtained average concentrations from the months of January through March do not exceed the limits for Class I water quality.

Comparing the seasonal changes in the average concentrations of total nitrogen in each measurement period, it is noted that the content decreases in July and the total nitrogen pool is rebuilt in autumn and winter. Analysis of the spatial distribution of total nitrogen concentrations in the surface and bottom layers shows a fairly even distribution of concentrations in the study area of OWF BIII.

Phosphate content in samples from the IMF BIII field ranged from below the limit of quantification (0.132 $^{pmol\text{-}dm\text{-}3}$) to 1.633 $^{pmol\text{-}dm\text{-}3}$. Analysis of the spatial distribution of phosphate concentrations in water samples from the WBW III study area shows a similar distribution in the surface and bottom layers. The highest concentrations were found in October 2012 and February 2013. In the following months, phosphate content decreased in accordance with the seasonal cycle of nutrient variability. A period of intense phytoplankton blooms is followed by a gradual recovery of phosphate content during the autumn and winter.

The range of total phosphorus concentrations found in the analyzed water samples from the BIII offshore wind farm area ranged from values below the limit of quantification of 0.3 ^mol-dm-3 to 2,341 ^mol-dm-3. Analysis of spatial distributions of total phosphorus concentrations in the surface layer of water from the BIII OWF area showed the highest concentration in October 2012 in the southern part of the area, while in February and September 2013 in the northwestern part of the BIII OWF area. The observed differences in the spatial distribution of phosphorus are small, and on the basis of the scope of the study, it is not possible to say conclusively which factors had the greatest influence on the situation found. During the other periods as well as in the bottom layer, phosphorus concentrations were fairly evenly distributed. Analyzing the seasonal variability of phosphorus compounds in the waters of the study area, it was found that the highest phosphate concentrations in most of the analyzed water samples were found in February, a period when the biogenic pool in the Baltic Sea waters is restored.

The waters of the study area were characterized by low levels of particularly harmful substances. Concentrations of polychlorinated biphenyls, free and bound cyanides, metals (Pb, Cd, Cr, Cr(VI), As, Ni, Hg) and phenols were present at very low levels. The waters studied are also characterized by low values of ^{137Cs}and ^{90Sr}activity,-typical of southern Baltic waters and confirming the slow downward trend of ^{90Sr}and ^{137Cs}concentrations in the Baltic Sea area (Zalewska, 2012).

The mineral oil index value was also traceable.

In the BIII offshore wind farm area, concentrations of PAHs were observed that were slightly higher than the literature.

Comparing the obtained results of water testing with the limit values specified in the Regulation of the Minister of Environment of November 09, 2011 on the *method of classification of the state of surface water bodies and environmental quality standards for priority substances* (Journal of Laws 2011, No. 257, item.1545)[1], it is possible to classify the studied area of OWF BIII as water quality class I (very good condition) due to the content of dissolved oxygen at the bottom, BOD5, inorganic nitrogen compounds (in winter), total phosphorus and OWO (in summer), free and bound cyanides, mineral oil index, phenols and metals (As, Cr (VI), Cu). The waters of the study area also showed no exceedances of marine water quality indicator limits for PAHs (naphthalene, benzo(a)pyrene fluoranthene, the sum of benzo(b)fluoranthene and benzo(k)fluoranthene, and the sum of benzo(g,h,i)perylene and indeno(1,2,3,c,g)pyrene) as well as cadmium, lead, mercury and nickel.

Due to the slightly elevated average annual pH values of the tested waters, total nitrogen concentrations in the summer months and phosphate concentrations in the winter, the waters of the BIII OWF area were classified as Class II water quality, which means waters in good condition (based on the results of tests of physical and chemical indicators).

Also, according to the current regulation of the Minister of Infrastructure of June 25, 2021 on the classification of ecological status, ecological potential and chemical status, and the method of classifying the status of surface water bodies, as well as environmental quality standards for priority substances

[1] Despite the repeal of the aforementioned regulation, it was deemed reasonable to refer to the limits specified therein due to the fact that the cited studies were conducted during the period of its validity. At the time of the survey, there was no regulatory act relating to marine waters, so the results were referred to the limits for coastal waters.

(Journal of Laws of 2021, item 1475), the water quality of the basin is within the values specified for good water status.

The waters of the study area also did not exceed water quality indicator limits for average PAHs (naphthalene, benzo(a)pyrene fluoranthene, the sum of benzo(b)fluoranthene and benzo(k)fluoranthene, and the sum of benzo(g,h,i)perylene and indeno(1,2,3,c,g)pyrene) as well as cadmium, lead, mercury and nickel.

However, due to a slight increase in the average annual pH of the tested waters and the concentration of phosphates during the winter, the waters from the BIII OWF area were classified as water quality class II, that is, waters of good condition (based on the results of physicochemical tests).

Based on the results of the studies and analyses obtained, the BIII offshore wind farm area was also evaluated in accordance with the IODR, i.e., assessments of descriptive indicators of pressure W5 - eutrophication and W8 - pollutants. The evaluation of W5 indicators was based on the analysis of nutrients (DIP - phosphate phosphorus, TP - total phosphorus, DIN - soluble inorganic nitrogen, TN - total nitrogen and dissolved oxygen at the bottom). Based on the analysis, it is considered that the marine waters of the analyzed area are classified as below good status (sub-GES) - according to the classification in accordance with the IODR.

Sea currents

Seasonal variations in the values of current velocities are evident. The greatest variability was recorded in the layer at a depth of 0-4 meters below sea level. Such values of water flow were recorded during a strong storm in the Baltic Sea on 31.01 - 02.02.2013. The velocities of water flow in the deeper layers, oscillate between 0 and 50 cm/s and are characterized by much smaller amplitudes.

Waving

The most intense ripples occurred in autumn and winter, while the calmest were in spring and summer. The highest wave recorded was 6.14 meters high and the highest significant wave was 3.89 meters. The average wave height (calculated as the average of all recorded average waves) for point 001 was 0.57 m and for point 002 - 0.54 m. The wave motion was mainly from the west (W) and northeast (NE) directions.

Water temperature

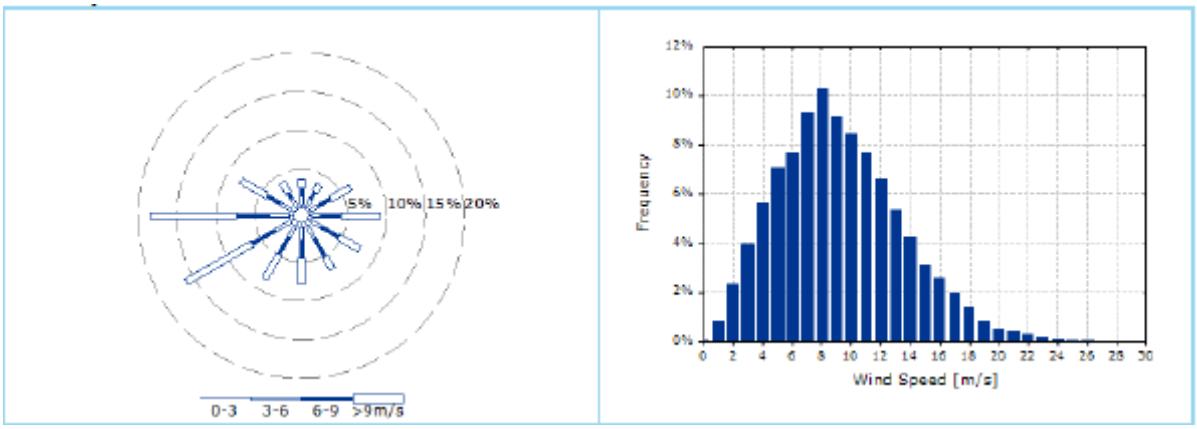
The temperature values do not deviate from the standard values for the entire measurement period. There were no extreme phenomena, deviating from the standard values for the South Baltic area (The Climate of Baltic Sea Basin, 1998). An increase in the average temperature of the Baltic Sea was observed (from 6.3°C to 7.8°C).

2.2. Indicators meteorological

Wind

Based on monitoring studies conducted for the project(Appendix C to the Report), the area of the planned BIII OWF is dominated by winds from the western and southwestern sectors with wind speeds above 9m/s, as shown below (Figure 1).

Figure 1. Wind rose and wind speed frequency distribution [m/s]



Source: (DNV GL 2019)

Wind speeds range from 0-5 degrees on the Beaufort scale. The period when winds of greater strength blow is autumn and winter, which coincides with the period of storms at sea, where wind speeds exceeded 20-23 m/s.

Air temperature

Air temperature had an annual pattern consistent with the average temperature pattern in the Baltic area (Climate of Baltic Sea Basin, 1998). The minimum value did not exceed -10 o, while the maximum temperature was less than 25°C. The area of open sea blurs the influence of the continent on thermal conditions. Winters are milder and summers are cooler. The possibility of ice phenomena in the area of OWF BIII is described as negligible.

2.3. Sea currents and undulations

The study made it possible to observe seasonal variations in the values of current velocities. The greatest variability was recorded in the layer at a depth of 0-4 meters below sea level. Such values of water flow were recorded during a strong storm in the Baltic Sea on 31.01 - 02.02.2013. Water flow velocities in the deeper layers, oscillate between 0 and 50 cm/s and are characterized by much smaller amplitudes.

The most intense ripples occurred in autumn and winter, while the calmest were in spring and summer. The highest wave recorded was 6.14 meters high and the highest significant wave was 3.89 meters. The average wave height (calculated as the average of all recorded average waves) for point 001 was 0.57 m and for point 002 - 0.54 m. Wave movement was mainly from the west direction

(W) and northeast (NE). The maximum differences in the levels of the mean free sea surface for both measurement points during the period in question significantly exceeded 1 m.

3. Summary

The parameters studied did not differ significantly from those characteristic of the South Baltic area, demonstrated both within the framework of the PMŚ and within the framework of studies conducted in areas designated for the construction of other wind farms.

The BIII offshore wind farm area, according to the HELCOM division of marine waters into sub-areas used for the implementation of the RDSM, lies within the Bornholm Basin sub-area. The waters of this

sub-acreage have been evaluated under the PME for, among other things, criteria related to water pollution:

D5 - evaluation of eutrophication based on analysis of the content of biogenic substances (phosphate, inorganic nitrogen, phosphorus and total nitrogen), as well as chlorophyll "a", seawater transparency and dissolved oxygen at the bottom,

D8 - hazardous substances in the environment.

Based on the analysis, it is considered that the marine waters of the analyzed area were classified as below good (sub-GES) in 2017, 2018 and 2019 (GIOŚ 2018, GIOŚ 2019, GIOŚ 2020).

Studies conducted for the BIII offshore wind farm area show similar marine water quality values to the results obtained for the Baltica 2 offshore wind farm area (IMG Consortium and MEWO et al. 2017) and the Baltic Power offshore wind farm (IMG Consortium and MEWO et al., 2020), which are adjacent to the Project.

OWF BIII / Project	Bałtyk Środkowy III Offshore Wind Farm
Report	The Environmental Impact Assessment Report for the purposes of the procedure finalized by the decision of the Regional Directorate for Environmental Protection dated July 7, 2016, ref. No. RDOŚ-Gd-WOO.4211.12.2015.KP.22

1. Introduction

The section presents a characterization of the seabed of the area of the planned BIII OWF, made on the basis of the results of studies conducted to determine the type of substrate for the Project.

In the BIII offshore wind farm area, a survey was conducted to describe: the depth of the bottom within the boundaries of the designated firing range, the nature of the bottom, the sediments present on its surface, and to identify the geological structure. Shallow boreholes were also drilled, from which core samples were taken to determine the type of bottom-building sediments.

During the course of the survey, data were collected, which were then used to create the following maps: bathymetric, sonar image of the bottom, maps of the depths of the various sediments. The methodology of the study and the results of the tests performed, along with their analysis, are presented in Appendix D of the Report.

The surveys carried out made it possible to determine the geological structure of the seabed - the type, geological structures and age of the sediments building the base of the planned project, and provided an opportunity to characterize the surface sediments of the seabed. Side-scan sonar measurements provided data showing an image of the bottom surface. The individual profiles were assembled into a sonar mosaic of the bottom. This image was the basis for determining sedimentary structures (accumulations of sediments arranged in characteristic forms): ripplemarks, sand waves and pebbles. Reconnaissance of the seafloor also made it possible to identify the presence of underwater objects.

The key conclusions of the research and analysis performed are presented below. The studies performed are considered sufficient, both in scope and timeliness, to determine the sensitivity of the environment and assess the environmental impact of OWF BIII (see Volume IV).

2. Characteristics of the seabed sea

The sculpture of the IMF BIII bottom is varied. The depth of the study area ranges from about 23.5 meters in the southwestern part to about 43 meters in the northwestern part. The slope of the bottom is relatively gentle. In the northwestern part, the relief of the bottom is varied - there are forms of ridges and depressions formed on the surface of clays. Denivelations within these forms reach about 3 meters. A bathymetric map of the area is shown in Figure 1.

The relief and geological structure of the BIII OWF field is related to the presence of the Scandinavian ice sheet, the subsequent deglaciation (disappearance of the ice sheet) of the area and the activity of modern processes on the seabed. Five areas with different bottom relief and different genesis were separated (Figure 2):

P1 - outcrop of glacial till with a variable sand and gravel cover, formed as a result of erosion processes associated with the thawing of this part of the bed;

P2 and P3 - complexes of kem terraces, formed at the moraine elevation near the front of the ice sheet, formed by the action of surface runoff, outflows of evaporative waters;

P4 - sW-NE runoff valley with numerous sill formations; P5 - accumulation plain (area of accumulation of glacial and marine sediments)

Figure 1. Bathymetric map of the OWF BIII area

The bottom surface of OWF BIII is represented by 5 types of bottom sediments separated on the basis of sonar images of the bottom. Featured:

- outcrops of glacial till,
- heaping clays with a thin cover of sands,
- marine sands,
- miscellaneous sediments,
- iles and mules.

Boulders and anthropogenic underwater objects, i.e. cables, ropes, nets, logs, anchors, barrels, have been marked on the sonar map, along with assigned geographical coordinates.

The layer of surficial sediments was described on the basis of geological interpretation of seismoacoustic profiles in relation to data obtained from side-scan sonar recordings. On the surface of the bottom there are mainly fine and medium-grained modern marine sands, constituting the so-called dynamic layer, which is subject to displacement under the influence of wave action. The thickness of this layer is variable, averaging from about 0.2 to about 1.7 meters.

As a result of the analysis, four main types of sediments were distinguished in the deep structure of the analyzed area: sands, differentiated sediments, clay/silt and glacial till.

Till clays are found in the deep structure of the entire fama. In the northern and northwestern parts of the study area, they form extensive outcrops, locally covered by a thin layer of sands and gravels.

In the relief of the clay subsoil, in the central part, an elongated hill with a SW-NE course is marked. On both sides of the hill are depressions filled with silty-clay sediments.

An extensive cover of sands, ranging in thickness from a few tens of centimeters to several meters, lies on the surface over a significant area of the study field.

Geological and geomorphological conditions of the BIII OWF area are considered (based on the reconnaissance so far) favorable for the foundation of OWF elements.

Report	The Environmental Impact Assessment Report for the purposes of the procedure finalized by the decision of the Regional Directorate for Environmental Protection dated July 7, 2016, ref. No. RDOŚ-Gd-WOO.4211.12.2015.KP.22

1. Introduction

The section presents a characterization of the occurrence of mineral resources in the area of the planned OWF BIII, in terms of assessing the potential suitability for exploitation of sedimentary accumulations (gravel, gravel-sand, sand-gravel and sand). The results of the Maritime Institute's field and laboratory surveys of the seabed, the results of laboratory tests of sediment samples were used for the analysis.

A methodological description of the raw material analyses performed and detailed results with a preliminary assessment are presented in Appendix E of the Report.

2. Characteristics of the occurrence of mineral resources minerals

In order to assess the operational suitability of sediment accumulations in the area of the Baltic III offshore wind farm, literature data and the collected results of field surveys of the seabed and laboratory tests performed in the area by the Maritime Institute were used, as well as the results of laboratory tests of sediment samples.

Sonar surveys and surface samples taken by the Maritime Institute in the study area show that there are accumulations of boulders and stones on the bottom surface, often preventing sediment sampling. There are also outcrops of glacial till, gravels, coarse-grained, medium-grained and fine-grained sands (up to a few centimeters thick) lying on glacial till, and fine-grained and very fine-grained sands.

In the northern part of the study area, there are coarser sandy-gravel deposits of small thickness (up to 30 cm) lying on clays. In the northwestern part on the surface of the bottom, there are clays. It is also an area of boulders and stones. In the eastern part, the thickness of sandy sediments (various grains) is greater than 1 m.

The research conducted allowed:

- ocontouring of potential deposits of raw materials .Due to the small fields of these sediments (gravelly sands) and the significant overburden (2 m) of mainly fine-grained and very fine-grained sands make these deposits unusable from a technological and economic point of view as of today;
- charting areas of boulder fields and outcrops of glacial till over a significant area, which deposits preclude the existence of accumulations of raw materials of a depositional nature on these surfaces;
- confirmation of the presence of sands in the southeastern part of the area. These are fine-grained and very fine-grained sands, which are not suitable for shoreline recharge.

Macroscopic analysis of cores taken during field surveys by the Maritime Institute and literature data showed the absence of heavy minerals in the sediments of OWF BIII. No amber was found in sediments taken from the OWF BIII field. Literature data exclude the study area as prospective for the exploration of amber deposits.

The area of OWF BIII partially overlaps with areas of hydrocarbon deposits (without the conflict of coexistence of the OWF and potential exploitation).

In the area of the planned offshore wind farm BIII and in its vicinity, there are no valid licenses for exploration, prospecting and production of hydrocarbons from deposits issued under the provisions of

the PGG.[1]

1. Introduction

The section presents the characteristics of bottom sediments as an important element of the Baltic Sea aquatic ecosystem. The results obtained from field and laboratory surveys of the seafloor (see Appendix D of the EIA) and the results of laboratory tests of surface sediment samples (see Appendix F of the EIA) were used for the analysis.

For the development of the Report, including the characterization of bottom sediments in terms of physical and chemical properties and sensitivity to potential impacts of the Project, the results of the following studies were used: moisture content, roasting losses, total content and labile form of metals (Pb, Cu, Zn, Ni, Cd, Cr, As, Hg), polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), mineral oils, ^{137Cs}radioactivity, tributyltin (TBT), and nutrient content (total nitrogen and total phosphorus).

The detailed results of the study, along with a description of the methodology used, are attached as Appendix F to the Report.

Based on the results obtained, the following are the key conclusions of the research and analysis performed. The studies performed are considered sufficient to obtain reliable and representative data for assessing the environmental impact of OWF BIII.

In addition, the summary refers to the results of surveys covering the northern part of the Project area carried out for the Baltica offshore wind farm project, as well as surveys carried out for the Baltic Power offshore wind farm project about 2 km away from the Project area.

2. Characteristics of the sediments bottom sediments

The construction of wind turbines (and in particular the laying of foundations) involves a great deal of disturbance to the bottom sediments, so there is a potential danger of releasing contaminants from the sediments into the water table and thus deteriorating water quality and its condition. The studies conducted in the aforementioned area allow estimating the potential impact on water levels, especially during the construction phase (see Volume IV, Chapter 2 of the EIA). The concentrations of the studied parameters will also serve as a background (reference) in monitoring studies conducted in the study area during the operation stage of the farm.

None of the tested sediment samples from the BIII offshore wind farm area exceeded the permissible concentrations of metals, PAHs and PCBs, as specified in the now-defunct (due to the repealed legal basis) Regulation of the Minister of Environment of April 16, 2002 on the *type and concentrations of substances that cause the excavated material to be contaminated* (Journal of Laws of 2002. No. 55, item 498). The study showed that the bottom sediments taken from the BIII OWF area are not hazardous in terms of the tested substances, and according to the Law on Waste of December 14, 2012, Article 2, item 7 (Journal of Laws 2021, item 779), they can be moved within the waters.

2.1. Moisture content and roasting losses roasting

The analyzed surface bottom sediments from the BIII offshore wind farm area collected in both June/July and November belonged to inorganic sediments with organic matter content expressed by loss on ignition (LOI) <10%. The average value of LOIs taken in June/July was 0.33% and 0.31% in November, indicating that the BIII OWF study area is located in an erosion bottom zone, where continuous physical activity of the waters causes sediment resuspension, i.e. the movement of insoluble sediment particles into the water table due to water movement (see Appendix F of the EIA).

2.2. Phosphorus general

According to the literature (see Appendix F of the EIA), the phosphorus content of the surface layer of Baltic sediments in the region of continuous accumulation of fine and dispersed sediments is higher than in the region of their transport and erosion.

The average concentration of phosphorus in the area of OWF BIII, was 265 mg kg $^{-1}$ s.m. in June/July and 264mg kg $^{-1}$ s.m. in November (from 145 to 784 mg kg -1 s.m.), respectively Higher concentrations of phosphorus (450-784mg kg $^{-1}$ d.m.) were observed in the northwestern and southwestern parts of the study area, where clayey sediments and sands on clays were found (see Appendix D and Appendix F of the EIA). In this type of sediment there is an easier accumulation of nutrients. Also, slightly higher concentrations of total phosphorus were found in the vicinity of the wreck (measuring stations BS3_504-BS3_507) - however, these are not concentrations above the level typical of Baltic Sea sediments (see Appendix D to the EIA).

The content of total phosphorus found in the analyzed sediments from the BIII offshore wind farm area in both measurement periods did not exceed the values typical for Baltic Sea sediments, which means that the sediments from the studied area are not rich in total phosphorus.

2.3. Nitrogen total

The main source of nitrogen in sediments is organic matter. Nitrogen in organic combinations is usually the dominant form of this element in bottom sediments. Inorganic forms of nitrogen are known as exchangeable and bound nitrogen. Exchangeable nitrogen represents ammonia adsorbed on the surface of clay minerals and/or organic matter. This form is easily displaced by other cations. Bound nitrogen is ammonia adsorbed to the interior of the crystalline structure of clay minerals and only marginally subject to ion exchange.

The average concentration of total nitrogen in the area of the planned project was 792 mg N kg $^{-1}$ d.m. in June/July and 616 mg N $^{kg-1}$ d.m. in November, respectively. Higher concentrations of total nitrogen were observed in the northern and northwestern parts of the BIII OWF area, where clayey sediments and sands on clays were found (see Appendix D and Appendix F of the EIA). In this type of sediment there is an easier accumulation of nutrients.

The content of total nitrogen found in the analyzed sediments from the BIII offshore wind farm area during the study period is comparable to the concentrations determined for Baltic Sea sediments.

2.4. Metals - total content

Heavy metals, migrating from the environment in various ways to surface waters (from anthropogenic sources as well as due to natural geochemical processes), are mainly deposited in bottom sediments. Despite their temporary immobilization, they pose a potential threat to biological life in a given reservoir, since under favorable conditions metals can be released from the sediment into the water depths, enter the trophic chain of the ecosystem and, as a result, restart their circulation in the environment.

The content of metals in the bottom sediments of the study area occurred at relatively low levels.

The distribution of concentrations of the elements studied was more or less evenly distributed throughout the study area. Slightly elevated metal concentrations were observed in the northwestern and southwestern parts of the farm area, where clayey sediments and sands on clays were found. No elevated concentrations of metals were observed in the area of the wreck.

The tested sediments were characterized by low heavy metal contents. Concentrations of mercury and cadmium were present in most of the sediment samples collected, below the lower limit of quantification, which for mercury was 0.01 $^{mg\text{-}kg\text{-}1}$ d.m., while for cadmium was 0.05 $^{mg\text{-}kg\text{-}1}$ d.m. The concentration of lead ranged from 0.96 to 7.40 $^{mg\text{-}kg\text{-}1}$ d.m., copper from 0.25 to 45.0 $^{mg\text{-}kg\text{-}1}$ d.m., nickel from 0.38 to 11.82 $^{mg\text{-}kg\text{-}1}$ d.m., arsenic from less than 1.25 to 5.05 $^{mg\text{-}kg\text{-}1}$ d.m., while the concentration of zinc in the tested sludge did not exceed 60 $^{mg\text{-}kg\text{-}1}$ d.m.

In the studied area of OWF BIII, the concentrations of analyzed metals (lead, copper, zinc, nickel, cadmium, chromium, arsenic, mercury) did not exceed typical values for sandy sediments of the southern Baltic Sea shown in the literature.

2.5. Metals - form labile

In terms of persistence and physical-chemical linkages, the way metals are bound to the sediment can generally be divided into two main groups: the part permanently bound in the crystal lattice - mainly to aluminosilicates, and the mobile (labile) part of metals susceptible to transition under natural conditions to the water table.

In order to assess how much of the metals from the bottom sediments from the BIII offshore wind farm area may pass into the water depths, the percentage of the labile form of each metal relative to its total content was calculated. This analysis showed that in the BIII OWF area in question, more than 70% of the lead and 54% of the copper present in the studied sediment can pass from the sediment to the water depth under favorable conditions. Zinc, nickel and chromium present in the tested sludge are mostly bound to it in a permanent manner. Only 31% of Zn, 36% of Ni and 29% of Cr can pass from the sediment to the water table under favorable conditions.

None of the tested sediment samples from the area of OWF BIII exceeded the permissible values of metals specified in the repealed Regulation of the Minister of Environment dated 16.04.2002 on the *type and concentrations of substances that cause the spoil to be contaminated (Journal of Laws No. 55, item 498)*. The limits (specified in this regulation) for individual metals are respectively: Hg (1.0 $^{mg\text{-}kg\text{-}1s}$.m.), Pb (200 $^{mg\text{-}kg\text{-}1s}$.m.), Cu (150 $^{mg\text{-}kg\text{-}1s}$.m.), Zn (1000 mg-kg-1s.m.), Ni (75 $^{mg\text{-}kg\text{-}1s}$.m.), Cd (7.5 $^{mg\text{-}kg\text{-}1s}$.m.), Cr (200 $^{mg\text{-}kg\text{-}1s}$.m.), As (30 $^{mg\text{-}kg\text{-}1s}$.m.).

2.6. Polycyclic aromatic hydrocarbons (PAHS)

Polycyclic aromatic hydrocarbons are compounds containing only carbon and hydrogen arranged in 2 - 13 aromatic rings adjacent to each other in the form of a "honeycomb." They are mainly formed as by-products of many processes, both natural and anthropogenic. Natural processes include forest and grassland fires, volcanic activity, geochemical reactions (e.g., the transformation of organic matter leading to the formation of oil). Anthropogenic processes are: burning of pastures and ditches, industrial processes, mainly related to the burning of oil and coal (refineries, coking plants, power plants and combined heat and power plants), household furnaces, automobile exhaust, waste incinerators, the plastics and dye industry, abrasion of automobile tires, emergency spills of oil and liquid fuels, cigarette smoke or home barbecues.

PAHs are found in all elements of the environment, and can enter bottom sediments along with atmospheric pollutants (dust), sewage and runoff, sediment and sewage water from storm sewers, ballast water, oil pollutants from associated with normal ship operations, and substances introduced during oil spills. The accumulation of PAHs in sediments is favored by, among other things: a high proportion of the muddy and clay fraction of the sediment, characterized by a large specific surface area and a high ability to retain hydrophobic pollutants on its surface, as well as a high content of humic substances and organic phosphorus, sulfur, nitrogen compounds (see Appendix F of the EIA).

All samples collected in the BIII offshore wind farm area from the surface layer of bottom sediments are characterized by low concentrations of tested PAH analytes, ranging from 0.001 to 0.086 $^{mg\text{-}kg\text{-}1s}$.m.

The obtained results of the analyzed PAH ratios may indicate that the source of surface sediment pollution in the study area is atmospheric deposition of pollutants from combustion processes (dust). The exceptions are the three samples taken at BS3_119, BS3_134 and BS3_506, where the concentration ratios indicate a petroleum origin of the analytes. One of these samples (BS3_506) was taken at the site of the detected wreck, where residues of petroleum products may have been present (see Appendix F of the EIA).

The concentrations of PAHs from the study area were compared with the limits determining the degree of contamination of the excavated material, which are presented in the repealed Decree of the Minister of the Environment dated 16.04.2002 *on the type and concentrations of substances that cause the excavated material to be contaminated* (Journal of Laws No. 55, item 498).

The comparison shows that the concentration of none of the PAHs listed in the above regulation was exceeded for any of the sediment samples taken.

2.7. Polychlorinated biphenyls (PCBS)

PCBs do not occur in nature as natural chemical compounds, and their appearance in the environment is the result of unintentional or inappropriate human activity, as a result of which PCBs entered the environment after a period of widespread use and increased production. Currently, their production has been halted and measures have been taken to reduce the associated environmental risks.

Significant amounts of these compounds are transported by air currents, are leached by rains, transported by surface water, and leached from the soil into water. As a result of atmospheric transport and river runoff, PCBs have entered marine and oceanic ecosystems. They become trapped on the surface of organic particles suspended in the water and enter the bottom sediments as a result of falling. Their accumulation in sediments is favored by a high proportion of the silty and clay fraction (< 0.063 mm) and a high content of organic matter (> 10%) (see Appendix F to the ROOŚ, per: Bolalek (ed.), 2010).

The obtained results of PCBs in bottom sediments from the BIII offshore wind farm area do not deviate from the literature data on PCBs in surface bottom sediments of the southern Baltic Sea, while being in their lower range, indicating a recent decrease in the concentration of these compounds.

The concentrations of total PCBs from individual points were compared with the limits determining the degree of contamination of the excavated material, which are presented in the repealed Decree of the Minister of the Environment dated 16.04.2002 on the *type and concentrations of substances that cause the excavated material to be contaminated (Journal of Laws No. 55, item 498)*.

The comparison shows that the concentration of the sum of seven congeners (i.e., "substances of the same type" denoted by the letter abbreviation of their name and assigned consecutive number) of PCBs (Nos. 28, 52, 101, 118, 138, 153, 180) (0.3 mg-kg-1 s.m.) was not exceeded for any of the samples taken from the BIII OWF study area (see Appendix F to the EIA).

2.8. Oil mineral

The largest source of oil pollution is land-based runoff from contaminated process water from industrial plants, water after washing motor vehicles, and from the flushing of fuels and oils lost by cars on paved

parking lots and streets. The second major source of oil is the normal (and therefore trouble-free) operation of ships, including sports vessels. Only in third place (globally) are tanker disasters. They are not much inferior to oil pollutants introduced by the atmosphere, coming mainly from incomplete combustion of liquid fuels in engines and boiler or thermal power plants. Natural sources, i.e. seepage through cracks in the earth's crust and seepage of oil through permeable layers, come next. In last place is the extraction of oil from beneath the seabed, i.e. the activities of exploration and production platforms (see Appendix F of the EIA, after: Gierak, 1995; Fabisiak, 2008; Korzeniowski, 1998).

In the study area, the concentration of mineral oil was low, while no oil above the analytical method's limit of quantification was found in samples taken in the area of the detected wreck.

The low values of the determined concentrations correlate with the low content of organic matter in the studied sediments and are adequate to the geological structure of the studied sediments (sands and gravels), which do not have the capacity to retain the compounds in question (see Appendix F to the EIA).

2.9. Radionuclides

The level of radioactivity in the Baltic Sea is mainly shaped by the presence of isotopes of cesium (^{137}Cs) and strontium (^{90}Sr). Both isotopes were prevalent in the marine environment both before the Chernobyl nuclear power plant accident in 1986 and today. They are isotopes of entirely anthropogenic origin and are characterized by long half-life times.

Sediments in the study area were also characterized by low radioactive concentrations of ^{137}Cs typical of sandy sediments. These concentrations varied from 1.1 to 6.61 Bq $^{kg-1}$ and were typical of sandy sediments of the southern Baltic Sea (with low organic matter and fine (silty) fractions, conducive to radionuclide accumulation).

According to the literature (see Appendix F of the EIA), the radioactive concentrations of ^{90}Sr in muddy sediments remain far lower than those of ^{137}Cs. Therefore, it is expected that in the case of sediments with a dominant sand fraction (which is the case for the OWF BIII area), ^{90}Sr concentrations will remain below the quantification threshold. This was the basis for abandoning the analysis of ^{90}Sr in sediments from the area of the planned farm, deeming it unfounded.

2.10. Tributyltin (TBT)

Organotin compounds belong to the group of organometallic compounds. The main environmental contamination with organotin compounds comes from anthropogenic sources, where they are used in particular in the production of polymers (70%), as biocides (20%), for the production of organometallic derivatives (7%). In the environment, organotin compounds are formed only in negligible amounts by biomethylation.

TBT concentrations in the study area were at low levels (generally below 0.01 mg-kg$^{"1}$ d.m.), characteristic of sandy sediments in the southern Baltic region.

Elevated TBT concentrations are generally found in sediments located in ports, harbor channels, shipyards and near waterways.

3. Summary

As a result of the study, it was found that the surface bottom sediments from the Project area belong

to inorganic sediments with an organic matter content of less than 10%. Concentrations of total phosphorus and total nitrogen do not exceed values typical of biogenic substances in the sediments of the southern Baltic Sea. Tested sediments from the Project site were characterized by low levels of heavy metals. All samples were characterized by low concentrations of the tested PAH analytes, which did not exceed values typical for the sediments of the southern Baltic Sea.

The results of the concentrations of the sum of the seven PCB compounds were mostly below the method's limit of quantification. The results obtained do not differ from the literature data on PCBs in the surface bottom sediments of the southern Baltic Sea, and, being in their lower range, indicate a decrease in the concentration of these compounds over time. The concentration of mineral oil was low in the study area. The oil concentration results for most samples are also mostly below the lower limit of quantification of the method.

The sediments studied were also characterized by low radioactive concentrations of 137Cs typical of sandy sediments of the southern Baltic Sea. TBT concentrations in the study area were also at low levels, typical of sandy sediments in the southern Baltic region.

None of the sludge samples tested exceeded the permissible concentrations of metals, PAHs and PCBs, as specified in the Ordinance of the Minister of the Environment of May 11, 2015 on the recovery of waste outside installations and facilities (Journal of Laws, item 796).

The study showed that the bottom sediments taken from the BIII OWF area are not hazardous in terms of the tested substances, and according to the Law on Waste of December 14, 2012, Article 2, item 7 (unified text Dz. U. of 2022, item 699) may be moved within the waters.

In addition, during the surveys carried out in 2016-2017 for the Baltic offshore wind farm project, the northern section of the Project area was surveyed for bottom sediments. As a result of the study, it was found that the analyzed surface bottom sediments from the study area belong to inorganic sediments with an organic matter content [expressed by loss on ignition (LOI)] of less than 10%. The content of biogenic substances (total phosphorus and total nitrogen) in the study area did not exceed the values typical of southern Baltic sediments. Concentrations of persistent organic pollutants (i.e., PAHs, PCBs, TBT) and harmful substances, such as metals and mineral oils, in the study area were low and did not generally differ from literature data for sandy bottom sediments of the southern Baltic Sea. The sediments studied were also characterized by low radioactive concentrations of 137Cs typical of sandy sediments. Thus, the results of the surveys conducted for the Baltic offshore wind project were in line with those done for the Project. It is also worth mentioning that analogous results to those for the Project area were obtained during bottom sediment surveys carried out in 2018-2020 for the Baltic Power OWF project, which is about 2 km away from the Project area, indicating similar characteristics of the condition of bottom sediments in the Project area.

Abbreviations and definitions

IMF	Offshore wind farm
OWF BIII / Project	Bałtyk Środkowy III Offshore Wind Farm
IMF Baltica	Baltica offshore wind farm
Baltic Power OWF	Baltic Power offshore wind farm
Phytobenthos	plants that are at least a few millimeters in size, and include vascular plants (Angiospermae) rooted in the bottom (e.g., seagrass) and macroalgae that attach themselves to hard surfaces (pebbles, wrecks, breakwaters), float freely on the bottom or float in the water's depths
Macrozoobenthos	synonym: benthic macrofauna, is the fraction of organisms that inhabit the surface of the bottom sediments (epifauna) or their interior (infauna), which, after washing, remains on a sieve with a mesh size of 1.0 mm (HELCOM 1988)

1. Introduction

The section presents a characterization of the benthos found in the area of the planned OWF BIII and in its vicinity. The characterization in question was developed primarily on the basis of the results of surveys conducted in the area of the planned farm and in the buffer zone by the Maritime Institute in 2013. The research was conducted by video inspection. The results of the study, along with a description of the study area, its scope and the methodology used, are attached as Appendix G to the Report.

The results of surveys carried out in areas adjacent to the BIII offshore wind farm area for the environmental impact assessment of the Baltica offshore wind farm, Baltic Power offshore wind farm and State Environmental Monitoring projects were also used to develop this section.

2. Characteristics of the benthos in the OWF area BIII

2.1. Phytobenthos

Phytobenthos surveys were conducted only on rocky bottoms for macroalgae.

The basis for determining the location of the phytobenthos-macroalgae video inspection was the analysis of bathymetric and sonar maps, as well as images from side-scan sonar bottom measurements taken during phytobenthos surveys. This made it possible to initially identify the characteristics of the sediments and the shape of the bottom. As the maximum range of macroalgae in the Baltic Sea is 22 m, the locations for the video survey were determined on hard bottom (boulders, pebbles) not exceeding 25 m depth.

Due to the depths found in the area of the planned OWF BIII and in its vicinity (about 20-40 m), which exclude the presence of rooted plants (recorded in the Baltic Sea to a depth of 10 m), phytobenthos research was conducted only for the presence of macroalgae on the rocky bottom. The designated sites of potential macroalgae occupied only 1% of the study area and were located in the southwestern part of the buffer zone. Video inspection was carried out at 20 video locations selected for this purpose using a remotely operated underwater vehicle ROV.

Surveys revealed the presence of filamentous brown algae (probably common in Polish marine areas *Pylaiella littoralis* and/or *Ectocarpus siliculosus*) and filamentous kelp (probably of the Rhodomelaceae family) in the buffer zone. During the analysis of the footage in 5 locations, the species of the pleuroid crayfish *Furcellaria lumbricalis* (formerly *F. fastigiata*), which is under strict protection in Polish marine areas in accordance with the Regulation of the Minister of Environment of October 9, 2014 on the protection of plant species (Journal of Laws of 2014, item 1409), was also identified. The characteristics of the aforementioned phytobenthic species are presented in Table 5.1 in Appendix G of the Report.

The macroalgae identified during the survey in most cases (82% of the locations where they occurred) were overgrowing unattached aggregations of mussels on the bottom, moving freely on the sand with the sea currents. Accordingly, the filamentous brown algae and kelp overgrowing the mussel beds on the sandy bottom (including the only protected species, *Furcellaria lumbricalis*), were considered temporary vegetation in the area of the planned farm.

Macroalgae attached to solid substrate (pebbles and boulders) were found in the buffer zone of the BIII offshore wind farm in only two locations, in the 23-25 m depth range. It was a filamentous kelp, most likely from the family Rhodomelaceae, which overgrew the bottom very sparsely, in the form of single specimens sparsely distributed on the bottom (bottom coverage <1%).

The results of the survey indicate that both the area where the BIII OWF is planned and the surrounding

buffer zone are not valuable in terms of phytobenthos. This is due to the unfavorable environmental conditions for phytobenthos development prevailing in the study area, i.e. great depths and limited availability of hard substrate, overgrown primarily with mussels.

In 2016, phytobenthos surveys were also conducted in the body of water located in the vicinity of the BIII offshore wind farm area designated for the Baltic offshore wind farm. The survey showed trace presence of phytobenthos, only in the southwestern part of the Baltica OWF area, so at a considerable distance from the area of the planned BIII OWF, outside the zone of its potential impact. Single specimens of macroalgae were represented by 6 taxa previously recorded in the South Baltic: the brown algae *Sphacelaria sp.* and *Pylaiella littoralis* , and the kelp *Rhodomela confervoides, Coccotylus truncatus, Aglaothamnion tenuissimum,* and *Furcellaria lumbricalis* (IMG Consortium and MEWO et al. 2017).

Surveys conducted in 2018-2020 in the adjacent area designated for construction of the Baltic Power offshore wind farm did not reveal the presence of phytobenthos.

In the area of the planned offshore wind farm BIII, in the northern part of Slupsk Shoal, a macrophytobenthos monitoring station is located within the framework of the State Environmental Monitoring (LS station). During the surveys conducted in 2020 on Slupsk Shoal, as in previous years, representatives of kelp*(Vertebrata fucoides, Coccotylus truncatus, Ceramium diaphanum, Ceramium sp., Furcellaria lumbricalis*) and brown algae*(Ectocarpus siliculosus, Desmarestia viridis*) were most common (GIOŚ 2021). Dwarf algae on the surveyed profile accounted for more than 90% of the total biomass in June and 100% in September.

2.2. Macrozoobenthos

Macrozoobenthos samples from the sandy bottom were taken with a van Veen-type scoop in a regular kilometer grid. Samples of epiphytic macrofauna from the rocky bottom were taken with a grabber equipped with a remotely operated underwater vehicle.

In the basin encompassing the area of the planned offshore wind farm BIII and its vicinity, 27 species and higher (not designated to species) taxonomic units of benthic macrofauna were found, of which crustaceans were the most abundant, with 12 taxa. However, no rare or protected macrozoobenthos species were found during the survey. Absolutely constant taxa included: *Hediste diversicolor, Pygospio elegans, Marenzelleria neglecta* , and *Limecola balthica* (in Appendix G of the Report under the name *Macoma balthica*). The characteristics of the macrozoobenthos species found in the study area are presented in Table 5.4 in Appendix G of the Report.

Based on the qualitative and quantitative composition of the benthic macrofauna as the basic features of the grouping structure, two macrozoobenthos communities were distinguished in the study area. Syndrome I mainly inhabited the northwestern, deepest part of the study area, where the bivalve Mytilus trossulus - a major component of the diet of benthic birds - dominated in terms of abundance. Syndrome II occurred in the shallower part of the area on sandy sections of the bottom. The dominant species in terms of abundance in this assemblage was the sandy polychaete Pygospio elegans, living in tubes made of agglomerated sand grains.

The taxonomic composition, abundance and biomass of macrozoobenthos in both assemblages were typical of the shallow to intermediate deep bottom of the open zone of the southern Baltic Sea. Both separated assemblages were characterized by a similar degree of natural valuation, expressed by the value of the macrozoobenthos B multimetric index (3.01 and 3.05, respectively).

These values, in accordance with the Regulation of the Minister of Environment of March 29, 2021 *on the adoption of a set of characteristics typical of good environmental status of marine waters* (Journal

of Laws, item 568), indicate good environmental status of waters with respect to characteristics: 1 (concerning the maintenance of biodiversity), 5 (concerning the minimization of eutrophication caused by human activities) and 6 (concerning the maintenance of the integrity of the seabed at a level that ensures the protection of the structure and function of benthic ecosystems and the absence of negative impacts on these ecosystems) (the limit value of the indicator set by the regulation for all these characteristics is ≥ 3.18).

According to the Decree of the Minister of Maritime Affairs and Inland Navigation of June 25, 2021 *on the classification of ecological status, ecological potential and chemical status, and the method of classifying the status of surface water bodies, as well as environmental quality standards for priority substances* (Journal of Laws of 2021, item 1475), the values of the multimetric indicator of macrozoobenthos B determined for both complexes correspond to water quality class III (moderate ecological status). Based on the regulation on the environmental status of marine waters, only two environmental statuses of marine waters can be distinguished - good and below good. It should be mentioned here that good status in accordance with the Regulation on the Environmental Status of Marine Waters includes Class I and II of coastal water quality (very good and good ecological status, respectively) from the Regulation on the Status of Surface Water Bodies, while below good status includes the other classes.

The result of the valorization of the area based on the evaluation of macrozoobenthos assemblages is shown in Figure 5.22 in Appendix G of the Report. Although this valorization was made on the basis of the Regulation of the Minister of Environment of November 9, 2011 on the method of classifying the state of surface water bodies and environmental quality standards for priority substances (Journal of Laws No. 257, item 1545), which was in effect during the period of the study, it is up to date with respect to the currently effective Regulation of the Minister of Infrastructure of June 25, 2021. on the classification of ecological status, ecological potential and chemical status and the method of classifying the status of surface water bodies, as well as environmental quality standards for priority substances (Journal of Laws No. 1475), as the limit values for coastal waters used for valorization have not changed.

The regions with the highest natural values in terms of macrozoobenthos (very good and good status according to the regulation on the status of surface water bodies = good status according to the regulation on the environmental status of marine waters) were dominant in the southern, sandy part of the study area. They occupied nearly 20% of the BIII OWF area.

In 2016, zoobenthos surveys were conducted in the body of water located in the vicinity of the BIII offshore wind farm area designated for the Baltic offshore wind farm. As a result of the surveys, 33 zoobenthic taxa were found in the Baltic Sea Area. The predominant taxa were those typical of shallow and medium-depth bottoms (up to 50 meters above sea level) of the open waters of the South Baltic. Absolutely constant species included the polychaetes *Marenzelleria sp.* and *Pygospio elegans* , as well as the Baltic horned clam *Limecola balthica*, which has a wide range of tolerance to environmental factors, the antinella *Bylgides sarsi*, and the common midget *Diastylis rathkei* (IMG Consortium and MEWO et al. 2017). Three of them were also among the most common macrozoobenthos taxa identified during surveys of the area of the planned OWF BIII and its vicinity.

On the other hand, in 2019, surveys were conducted at the Baltic Power offshore wind farm site adjacent to the east. In the area, 25 taxa belonging to one type, six clusters and one subcluster were found on the soft bottom, among which the polychaetes *Marenzelleria sp.* and *Pygospio elegans* were among the absolutely constant species. Sixteen taxa belonging to six clusters and one subcluster were recorded on the hard bottom. The abundance and biomass structure there was dominated by the mussel Mytilus sp. ((IMUMG Consortium and MEWO et al. 2020).

The closest shallow-water location to the BIII OWF area for monitoring of benthic macrofauna within the framework of the National Environmental Monitoring is in the area of Slupsk Shoal (station P14B), while the closest deep-water location is in the area of Slupsk Trough (station P3). During the survey

conducted in 2020 at the site in the area of Slupsk Shoal, a good condition of macroozoobenthos was found. However, in the case of the site located in the Slupsk Trough area, 2020 was another year during which a decrease in the value of the B index was recorded, so that the status decreased from good to moderate, below the limit of good status as defined by the IODC (GIOŚ 2021).

Ichthyoplankton	Floating in the depths of water early stages of fish: eggs and larvae

1. Introduction

This section presents a characterization of the ichthyofauna found in the area of the planned offshore wind farm OWF Central Baltic III and in its vicinity. The characteristics in question were developed primarily on the basis of the results of surveys conducted in 2012-13. The results of the study, along with a description of its scope, study area and methodology used, are attached as Appendix H to this Report.

The results of surveys conducted in areas adjacent to the BIII offshore wind farm area, carried out for the environmental impact assessment of the Baltica offshore wind farm and the Baltic Power offshore wind farm, were also used to develop this section.

2. Characteristics of ichthyofauna in the OWF area BIII

Studies of ichthyofauna were conducted in the area of the planned construction and operation of OWF BIII and in the 1 Mm buffer zone, over a period of one year. From the fall of 2012 to the summer of 2013, 5 series of surveys were conducted, covering all seasons. To determine the temporal variability of pelagic and demersal fish assemblages in the OWF and buffer zone, 10 research cruises were carried out, including five targeting pelagic fish (mainly herring and sprat) and ichthyoplankton, and five targeting demersal fish (mainly cod and flatfish).

Fifteen species of fish were found in the study area. In ichthyoplankton samples collected with a Bongo net, 10 taxa of fish larvae and sprat eggs were recorded. Of all the fish species encountered, species (sprat, herring, cod, flounder, plaice, turbot) are commercially caught by Polish fishermen, but only 4 of them (sprat, herring, cod and flounder) were more abundant in the survey catch. The abundance of other fish species was low or incidental, ranging from one individual (coalfish, beluga) to 43 individuals (sandeel). A complete list of ichthyofauna species caught during surveys in the area of OWF BIII and its vicinity, subject to differentiation into eggs and larvae (ichthyoplankton) and adult fish, is presented in Table 5.1.1 in Appendix H of the Report.

In the survey catch, sprats (77.9%) were the most abundant species found in the BIII OWF and buffer zone, followed by cod (9.5%), herring (7.6%) and flounder (4.4%). The pelagic trawl fishery was dominated by sprats and herring, while the pound net fishery was dominated by cod and flounder. In terms of weight, cod clearly dominated the survey catch (56.3% of the total weight of fish caught), followed by flounder and sprat. No adult protected or endangered fish species were found throughout the study period.

A total of 9 fish species were recorded in pelagic fisheries during the study period. In addition to the dominant species (sprat and herring), cod, beluga, sandeel, tobaccos, haddock, mackerel and stickleback occurred in small numbers. The abundance of herring and sprat varied from one study period to another, with the highest biomass and abundance of pelagic fish (nearly 207 million individuals of sprat and 12 million of herring) estimated in the summer (July) of 2013, a period when herring and sprat moved through the study area to feeding grounds. With regard to herring, the study area at the end of summer contained only juveniles, mainly from the generation of recruits (age group 0), a relatively high proportion of which (about 37% of abundance) was also recorded the previous autumn. Despite the fact that shallow waters, primarily in the 30-60 m isobath interval, are a natural place for juvenile fish of herring species to grow up, the low density of their concentration in the study area, as well as their poor feeding intensity, testified to the low suitability of these waters as feeding grounds during the season in question. This was the only period in which the surface density of pelagic resources was higher than the multi-year average for the Polish Marine Areas. During the other study periods, the surface density of pelagic fish was many times lower than the multi-year average. Small numbers of herring and sprat occurred in the study area in autumn 2012 and late summer (September) 2013. Only single

individuals of herring and sprat were recorded during the winter (January) and early spring (March) of 2013. The spatial distribution of herring and sprat during their feeding and spawning migrations is much wider than the relatively small area the OWF is expected to occupy.

The bottom catches of the survey kits recorded the presence of 11 fish species, of which cod and flounder were the most abundant and in all survey periods. The abundance of these two species varied from one survey season to the next. Cod occurred most abundantly in the autumn (November) of 2012 and late summer (September) of 2013, where they accounted for 95% and 73% of the abundance, respectively, in catches conducted with bottom survey sets. Flounder was most abundant in winter (January - 68%). Due to the nature of the bottom and the favorable food base, the study area is a habitat and feeding ground for juvenile cod, while it is bypassed by adults during reproductive migrations to the spawning grounds in the Bornholm Deep. The offshore winter flounder area lies on the winter migration route of flounder from feeding grounds located in shallow coastal waters to spawning grounds in the Slupsk Trough, but is not a target spawning ground for the dominant deep-sea spawning flounder in the area, which is mainly due to salinity that is too low, not exceeding 7.7 PSU. During bottom set fishing, in addition to cod and stronia, plaice, herring and devil hen were recorded in smaller numbers, while the remaining species (turbot, sprat, tassel, eel, mackerel and saithe) occurred as single individuals.

Studies of ichthyoplankton (the floating early life stages of fish: eggs and larvae) revealed the presence of 10 taxa belonging to this group of organisms. The most abundant component of ichthyoplankton were the eggs and larvae of sprat, indicating the occurrence of a fairly intensive summer spawning of this species in the area of the planned project. The summer spawning phase usually takes place in a layer of water up to 50 m deep and with a salinity of 6-8 PSU throughout the southern Baltic Sea.

Of the remaining ichthyoplankton taxa, flounder larvae were the most abundant species, coming primarily from spawning that takes place in the Slupsk Trough. The role of the shallow bottom areas in the project area as spawning grounds for a small portion of the breeding population in the shoal area appears to be insignificant compared to the deep-water spawning areas.

A relatively important component of the autumn and summer ichthyoplankton in the study area were herring larvae, but their abundance in the area of the planned project during these periods was significantly lower than that usually observed on typical spawning grounds, testifying to the low intensity of reproduction. This is also confirmed by the lack of mature individuals and larvae in September, despite the fact that this is the autumn spawning period, and the temperatures recorded at that time were optimal for the reproductive process. These observations indicate that the study area is of little importance as a spawning ground.

An important result of the ichthyoplankton survey from the point of view of the natural values of the area of the planned project was the finding of larvae of two fish species under partial species protection listed in the Decree of the Minister of Environment of December 16, 2016 on the protection of animal species (Journal of Laws of 2016, item 2183, as amended): denfish and small goby. For some time after hatching, the larvae of both species have a pelagic lifestyle, so the presence of scattered larvae in the water depths may indicate the spawning of these species both in and near the OWF area. Dennik, which prefers a plant substrate for spawning, is most abundant in deeper waters in the eastern part of the Baltic, but is not found in the southwestern part. The larvae of this species spread very widely in the pelagial, and are sometimes encountered near the surface of the water. The little goby, on the other hand, prefers shallow waters with a sandy bottom covered with clam shells and rocks.

It should be noted that in the vicinity of the area of the planned project there is the Slupsk Shoal which provides more favorable conditions for spawning of bottomfish and goby: adequate depth and the presence of substrate that allows spawning, such as stones, macroalgae and empty shells.

In 2016/2017, ichthyofauna surveys were conducted in the body of water located in the vicinity of the BIII offshore wind farm area designated for the Baltic offshore wind farm. During the survey, a total of

19 taxa of ichthyofauna were caught in all survey gear, of which the permanent fish assemblages of the study area included cod, flatfish, herring, sprats, and sparse hen devils, skates, sandeels and eels. During pelagic control fishing, in addition to herring and sprat, few specimens of cod, sandeel, mackerel, anchovies, flounder, tasso and stickleback were caught. The bottom fishery was dominated by flounder and cod, while other species made up a small bycatch (plaice, devil hen, turbot, herring, haddock, sandeel, mackerel, foxtail, sprat). In the ichthyoplankton samples, 12 taxa were identified. During the survey, 27 gobies larvae were recorded, most likely belonging to the partially protected species of small gobies, as well as 16 larvae of the denworm, which is also partially protected in Poland (IMG Consortium and MEWO et al. 2017).

In contrast, 22 taxa of fish were caught in surveys conducted in the Baltic Power OWF area. Flounder and cod were the dominant species, with the remaining species constituting a small bycatch (sandeel, plaice, devil hens, foxes, moths, turbot, herring, skates, eels, whiting and dab) (IMUMG Consortium and MEWO et al. 2020).

Table 1 below shows a comparison of the species composition of the ichthyofauna found during surveys in water bodies covering the areas and neighborhoods of the BIII OWF, Baltica OWF and Baltic Power OWF, indicating the dominant species in pelagic and demersal fisheries.

* dominant species in pelagic fisheries during surveys of both areas of the OWF

** dominant species in bottom fishing during surveys of both OWF areas

[1] in the case of surveys conducted in the BIII OWF area, due to difficulties in determining sandeel larvae to the species level, they were determined to the family level. There are two species of this family in the South Baltic: the tobacconist and the sandeel (both of which were found in adult form during the survey in the study area).

[2] due to the difficulty of determining gobies fish larvae to the species level, they were determined to the family level. Taking into account the biology and environmental preferences of goby fish species found in the Baltic Sea, it can be assumed with high probability that the larvae caught belonged to the small goby species (Pomatoschistus minutus).

[3] according to the report on the environmental impact of the Baltic offshore wind farm (IMG Consortium and MEWO et al. 2017), tobias were found during ichthyofauna surveys carried out for its purposes, while based on the information contained in the documentation in question, it is not possible to determine whether this species was a component of the ichthyoplankton or whether its adults were found.

The species composition of the ichthyofauna found during the surveys in all three study areas was similar, with pelagic and demersal fisheries by far dominated by the same species, sprat and herring, and cod and flounder, respectively. The species in question also dominated commercial fishing in fishing squares N7, M7, N8 and M8 (according to data for 2013-2020), in the area where the BIII OWF is planned to be built. The characterization of the BIII OWF area in terms of fisheries, including the analysis of fishing data from the aforementioned squares, was presented in Chapter 13 of Volume III of the Report.

The assessment of ichthyofauna in open marine waters within the framework of the PMS is carried out on the basis of the LFI index relating to the community of fish in open waters observed in research fisheries carrying out demersal fish stock assessment tasks. This index reflects the overall size structure at the community level and is assessed based on the biomass of large fish. It is primarily a good indicator of human pressure on the marine ecosystem, but its value can also be affected by other environmental conditions, such as temperature or nutrient concentrations.

Data obtained in 2020 as part of the State Environmental Monitoring enabled an assessment of the LFI Large Fish Index. The LFI index refers to the community of open-water fish observed in survey fisheries performing demersal fish stock assessment tasks (Baltic International Trawl Surveys - BITS). For the

Baltic, the index covers only the community of groundfish excluding pelagic fish, considering 5 species: (cod, whiting, flounder, plaice, turbot). The fish size index reflects the overall size structure at the community level and is assessed based on the biomass of large fish[1]. It is expressed in CPUE (catch per unit of fishing effort). ICES Subarea 25, inside which the BIII OWF area is located, saw a significant increase in the LFI compared to last year (0.56 and 0.42, respectively). After a period of several years where the value of LFI remained low, a rather significant increase was found. The value of the LFI without cod has also increased and now stands at 0.19. Analysis of both indicators shows an increase in the biomass of large cod and large flounder in the population. Based on this, it can be concluded that there has been an improvement in the marine environment in terms of the proportion of large fish biomass in subarea 25. The LFI value obtained in 2020 is lower than the designated threshold value (0.56 and 0.80, respectively) (GIOŚ 2021).

[1] The term "large fish" means fish above the total length (longitudo totalis) defined specifically for each area. In the case of the Polish Marine Areas, "big fish" are individuals over 30 cm l.t

1. Introduction

This section presents the characteristics of seabirds in the area of OWF BIII and in the zone of its potential impacts. The characterization was developed primarily based on the results of seabird surveys conducted in the area of the planned farm and its buffer zone. A report with the results of the seabird surveys along with a description of the methodology used is attached as Appendix I.1 to the Report.

The section also presents, developed for the purpose of assessing the impact of the planned farm on the integrity, coherence and object of protection of Natura 2000 areas, the characteristics of seabird occurrence in the area of Slupsk Shoal. Slupsk Shoal, located at a distance of about 5.5 km from the area of the planned farm, is an area belonging to the Natura 2000 network of areas with the code PLC990001, designated to protect wintering populations of black guillemot and long-tailed duck.

For this purpose, the existing documentation of the area, the results of studies conducted for the impact assessments of wind farms planned in the Slupsk Shoal area, and the Monitoring of Wintering Seabirds under the PMS were used. A report with the results of seabird surveys in the Slupsk Shoal area, conducted in parallel with the surveys in the area of the planned OWF BIII and its buffer zone, along with a description of the methodology used, is attached as Appendix I.2 to the Report.

The section also presents the results of studies carried out for the environmental impact assessment of the neighboring area of the planned OWF Baltica, covering both the area of the said farm and its vicinity, as well as the area of Slupsk Shoal.

2. Characteristics of the occurrence of seabirds in the area of OWF BIII (excluding excluding Slupsk shoal)

The seabird group includes species of waterbirds that mostly reside in marine waters during the non-breeding season. Most of them reach their highest numbers in the high seas zone, located more than 1 km from the shore. The exceptions are gulls, which accompany fishing boats on fishing grounds and their occurrence in the open sea is strongly influenced by human activity.

The primary objective of the study was to determine the species composition, abundance, density and flight height of seabirds occurring in the area of the proposed farm or flying over it. In addition, birds associated with terrestrial environments were recorded flying over the project area. Data from these observations will be used to assess the impact of birds migrating and flying over the farm area.

The research was conducted in the area of the planned offshore wind farm OWF Bałtyk Środkowy III (OWF BIII) and in a buffer zone of 2 nautical miles from the boundaries of the area designated in the permit for the erection and use of artificial islands, structures and devices in Polish maritime areas (PSZW), during a 13-month campaign in 2012-2013. The period covered by the study was divided into 4 seasons covering consecutive annual periods of seabird life: summer, autumn migration, wintering and spring migration.

In the seabird group, the following species were identified (in order from highest to lowest abundance): long-tailed duck, silver-backed gull, scoter, alka, uhla, nucleus, yellow-legged gull, little gull, saddle-backed gull, black-throated diver, guillemot, three-tailed gull, red-throated diver, eider and sharp-tailed otter. The first five of the aforementioned species were found in numbers of more than 100 individuals throughout the year: long-tailed duck - 3,163 individuals, silver-backed gull - 2,294 individuals, scoter - 524 individuals, alka - 422 individuals, and scoter - 284 individuals.

All of the identified species of seabirds are, with the exception of the silvery gull, under strict protection in Poland in accordance with the provisions of the Decree of the Minister of Environment of December 16, 2016 on the protection of animal species (Journal of Laws item 2183, as amended). The silver-backed

gull enjoys partial protection under the aforementioned regulation. The black-throated and red-throated auror and the lesser black-backed gull are listed in Annex I of the EU Birds Directive, while two species - the long-tailed duck and the black-throated duck - are classified by the IUCN as endangered species in the vulnerable category - VU (vulnerable).

The two by far most abundant bird species found during the survey were the long-tailed duck and the silver-backed gull. The long-tailed duck was the most abundant species in the study area, and its share among all observed birds ranged from 16.5% in autumn, to 61.2% in spring. The silvery gull was the second most abundant species found during the survey. The proportion of silvery gulls among all observed birds ranged from 8.2% in spring to 73.8% in summer. The remaining species appeared infrequently and sparsely in the study area, and most of them were not associated with it and only flew over it.

In the study area, seabirds resided at low densities. The average densities of waterbirds in the area of the planned BIII OWF and in its vicinity were similar, and in none of the four phenological periods did they exceed the value of 15 os./ ^{km2}. In individual phenological periods, these densities were, respectively, for the farm and buffer area: in summer, 0.7 and 0.9 os./ ^{km2}; in autumn, 3.2 and 3.4 os./ km2; in winter, 13.1 and 10.6 os./ ^{km2}; and in spring, 8.5 and 9.2 os./ ^{km2}.

Since the distribution of birds in the study area in successive phenological periods was highly variable, it is difficult to isolate one part of the study area that is clearly preferred by seabirds. In summer and autumn, when avifauna abundance was low, densities of less than 5 os./ ^{km2} prevailed in the BIII OWF area, while slightly more birds were present north of the planned farm area in the buffer zone and beyond (see Figure 7 and Figure 1 below or Figure 2 and Figure 3 in Appendix I.1 of the Report). In winter, when seabird abundance was highest, the area of highest density of 50 to 87 os./ ^{km2} covered only a narrow strip in the western part of the buffer zone and overlapped only slightly with the area of the planned OWF BIII. During the winter, the distribution of avifauna in the study area was very uneven, with adjacent areas of different densities (see Figure 3 or Figure 4 in Appendix I.1 of the Report). In the spring, after a decline in the number of birds, their preference for the eastern part of the basin was marked (see: Figure 5 or Figure 5 in Appendix I.1 of the Report), with average densities at the sites of the highest concentrations of avifauna during this period already reaching only 35 os./ ^{km2}. The reason for the lack of preference to one part of the study basin is most likely due to the poor food base with low zoobenthic biomass.

In 2016-2017, adequate methods were used to carry out monitoring in the body of water intended for the Baltica OWF, adjacent to the BIII OWF area to the north (Baltica Area 3) and northwest (Baltica Area 2), and in its buffer zone. The study area overlapped partially with the area of seabird surveys conducted in 2012-2013 covering the BIII OWF area and the zone of its potential impacts. During the surveys, a total of 14 species of birds residing on the water were found, including 12 species associated with the marine environment (in order from highest to lowest abundance: long-tailed duck, alcid, nuthatch, silvery gull, black-throated diver, yellow-legged gull, uhla, little gull, guillemot, saddle-backed gull, scoter and red-throated diver), as well as two species of waterbirds rarely found at sea away from the coast (laughing stock - 1 os. and gray gull - 19 individuals). The total abundance of all observed birds residing along the transects in the Baltica OWF Area was 5129 individuals. The long-tailed duck was the most numerous, accounting for 69% of all birds found. The second most abundant species was the alka, accounting for 12% of the total avifauna grouping. Of the remaining identified species, only the common boar and the silver-backed gull still exceeded the 5% threshold for participation in the grouping. The distribution of birds in the study area during the fall and spring migration periods was similar. In the spring, higher densities (up to 50 os./ ^{km2}) were found in Baltica Area 3, while in Baltica Area 2 they reached only 5 os./ ^{km2}. In autumn, such differences between the two parts of the IMF Baltic Area no longer marked themselves. In the winter, densities of up to 5 os./ ^{km2} prevailed in most areas of the Baltic Sea Area. In the central part of Baltica Area 3 and to the south and southwest of Baltica Area 2, they were higher, reaching up to 20 os./ ^{km2}. There was also a marked increase in the density of birds in

the direction to the Slupsk Shoal, from 5 os./ km2 to 500 os./ km2 at the very border with the Slupsk Shoal area. During the summer, densities were low with maximum values reaching 5 os./ km2 (IMG Consortium and MEWO et al. 2017).

Taking into account that the areas of the above-described surveys performed in 2012-2013 (hereinafter: first surveys) and 2016-2017 (hereinafter: second surveys) partially overlapped, a comparison of the size and distribution of bird densities in each period in the common part of the study area was made on the basis of the resulting maps. On the other hand, it should be remembered that the location of the survey transects during the two surveys in the common part of their areas was not the same. In addition, the different ranges of bird densities adopted for the presentation of the results of the two studies (much wider in the case of the second study) cause difficulties in their interpretation. It should be noted that the fact that, the density of birds in the common study area according to the map, for example, was in the range from 10.1 to 100 per km2, does not mean that the maximum density found in the area was 100 per km2. Instead, it can be concluded on this basis that the densities in the area exceeded 10 os./ km2. Therefore, the analysis of the resulting maps was supported by the relevant information contained in the descriptive part of the report on the environmental impact of the Baltic offshore wind farm. Accordingly, this comparison is for illustrative purposes only.

In the fall, bird densities found in most of the common area were slightly higher during the first surveys. They ranged from 1 to 4.99 per square kilometer, while during the second survey bird densities in most of the area did not exceed 1 per square kilometer. During the first survey, the highest densities were found in the northwestern part of the common area (falling within the range of 5 to 9.9 wasps/km2, and in a small section - from 10 to about 36 wasps/km2), while during the second survey - in its western and southwestern and southeastern parts (ranging from 1.1 to 10 wasps/km2) (see Figure 1 and Figure 2).

Figure 1 Distribution of all seabirds in the BIII offshore wind farm area during the autumn season, determined from surveys conducted in 2012-2013. The values of average density (individuals/km2) are presented. The figure shows the Baltic offshore wind farm development area and the area of seabird surveys conducted in 2016-2017

In the common area during the winter period during the first surveys, bird densities were found to be in the range of 1 to 49.99 per km2. Over the majority of the area, densities ranged from 4.99 per km2, while their highest values - in the range of 10 to 49.99 per km2 - were recorded in the central and eastern parts of the area. During the second survey, densities in almost all of the common area were in the range of up to 10 s./km2. They were higher only in a small part of the area, located in its southwestern part, and ranged from 10.1 to 100 settlements/km2. A few small fragments were also found in the area, where bird densities were less than 1 per square kilometer (see Figure 3 and Figure 4). Taking into account that, according to the report for Baltica OWF, in winter in the central part of Baltica Area 3, bird densities were higher compared to those found in most of the Baltica OWF area and reached up to 20 os./km2 (IMG Consortium and MEWO et al. 2017), it is assumed that also in the common study area they did not exceed the above-mentioned values.

Figure 3 Distribution of all seabirds in the BIII offshore wind farm area during the winter, determined from surveys conducted in 2012-2013. Average density values ([individuals/km2]) are presented. The figure shows the Baltic offshore wind farm development area and the area of seabird surveys conducted in 2016-2017

In the spring, during the first surveys in the common area, bird densities were found to be in the range of 1 to about 22 os./km2. The lowest bird densities were found in the western part of the area, slightly higher in the central part, while the highest densities (above 10 os./km2) were highest in the eastern part. In the case of the second surveys, the densities found ranged from 1.01 to 100 settlements/km2, and areas with densities exceeding 10 settlements/km2 were found in the central and northeastern parts of the area (see Figure 5 and Figure 6). It should be mentioned here that the content of the report for the Batica offshore wind farm indicates that in spring higher densities of up to 50 os./km2 were found in the Baltica 3 Area (IMG Consortium and MEWO et al. 2017). Therefore, it can be assumed that also in the common study area the densities did not exceed the above-mentioned values.

Figure 5 Distribution of all seabirds in the BIII offshore wind farm area during the spring, determined from surveys conducted in 2012-2013. Average density values (individuals/km2) are presented. The figure shows the Baltic offshore wind farm development area and the area of seabird surveys conducted in 2016-2017

The densities of seabirds found during both surveys on the common portion of the basin during the summer were at similar, relatively low levels. The densities of birds in the area, according to the results of the first survey, were in the range of up to 5.31 per square kilometer, while the second survey was in the range of up to 10 per square kilometer. Nevertheless, since, as indicated in the report for the Baltic offshore wind farm, bird densities were low during the summer period with maximum values reaching 5 os./km2 (IMG Consortium and MEWO et al. 2017), it can be concluded that densities in the common area during the two surveys were within an analogous range. The density of birds during both surveys was higher in the northern part of the area (see Figure 7 and Figure 8).

Comparing the above-described results of the two studies for their common area, there were no significant differences in the use of the water body in question by seabirds.

In 2018-2019, another avifauna survey was conducted in the area adjacent to OWF BIII to the east, intended for the construction of the Baltic Power OWF. The survey recorded a total of 19 species of water-dwelling birds, including 13 species associated with the marine environment and six species of waterbirds rarely seen at sea away from the coast. Species associated with the marine environment are: long-tailed duck, silver-backed gull, bulbul, alka, uhla, saddle-backed gull, scoter, little gull, black-throated diver, yellow-legged gull, red-throated diver, guillemot, eider. On the other hand, observed species rarely seen at sea far from the coast are: gray gull, laughing stock, cormorant, coot, arctic tern, white-fronted goose (IMUMG Consortium and MEWO et al. 2020).

3. Characteristics of the occurrence of seabirds in the Slupsk Shoal Natura 2000 area PLC990001

According to the SDF prepared for the Slupsk Shoal PLC990001 Natura 2000 site in October 2002, and subsequently updated in October 2021, the subject of protection in the area is the wintering and passage populations of three seabird species: long-tailed duck*(Clangula hyemalis*), guillemot (*Cepphus grylle*) and uhla*(Melanitta fusca*). These populations are estimated as follows:

- long-tailed duck: overwintering 101,148-231,180 individuals, long-tailed duck 76,440-214,374 individuals,
- plunger: wintering 98-556 individuals, transient 72-461 individuals,
- uhla: wintering 5,565-23,611 individuals, transient 910-1,789 individuals.

Ornithological monitoring in the area of Slupsk Shoal was carried out in parallel with seabird surveys conducted in the area of the planned OWF BIII and in its vicinity, described in Section 2. A total of 31 species of waterbirds, including 15 species of seabirds and 12 species associated with the terrestrial environment, were found during all survey cruises made in the shoal area. The total abundance of all birds observed was 102,134 individuals (the average abundance per research cruise was 5,674 individuals), including 72,225 individuals during the seven cruises made during the winter months (the average abundance of seabirds per cruise was 10313.6 individuals). Among all the birds observed, the proportion of seabirds was as high as 99.5%, due to the long-tailed duck's very abundant presence in the study area. The long-tailed duck accounted for a total of more than 94% of all birds observed, and 95.9% during the wintering period. These ducks in December and February formed very large concentrations of more than 10,000 individuals spotted from the ship, and during a cruise made in the

second half of February 2014, exceptionally large groupings of this species of more than 23,000 individuals were observed.

In the group of seabirds on Slupsk Shoal, the following species were recorded (in order from highest to lowest abundance): long-tailed duck, uhla, silver-backed gull, scoter, scoter, alka, dabbler, black-throated guillemot, yellow-legged gull, saddle-backed gull, lesser black-backed gull, red-throated gull, sharp-tailed otter, eider and three-toed gull. The first five of the aforementioned species were found in numbers of more than 100 individuals throughout the year: long-tailed duck - 97,398 individuals, uhla - 2,660 individuals, silver-backed gull - 1,380 individuals, scoter - 213 individuals, and alka - 159 individuals.

Seabirds in the Slupsk Shoal area periodically stayed at high and very high densities. The average density of the entire grouping of waterbirds in the different phenological periods was: for summer 1.1 per thousand square meters, autumn 164.2 per thousand square meters, winter 251.5 per thousand square meters and spring 67.9 per thousand square meters. In autumn, winter and spring, the long-tailed duck accounted for more than 90% of all birds observed, hence this species had a decisive influence on the picture of changes in the abundance, density and distribution of avifauna in the study area. The highest concentrations of seabirds were encountered in February, at the end of the wintering period, when during the research cruise on about 60% of the area of Slupsk Shoal the density of the most numerous species - the long-tailed duck - exceeded the value of 100 os./km2.

The distribution of birds during surveys on Slupsk Shoal in successive phenological periods was variable. In summer, when avifauna abundance was very low and densities of less than 3 os./km2 prevailed on Slupsk Shoal, slightly more birds stayed in its eastern part (see Figure 2 in Appendix I.2 of the Report). During the autumn migration period, average densities locally reached 230 s./km2. The highest concentrations of birds were then observed in the northern

-eastern part of the area (see Figure 3 in Appendix I.2 of the Report). In winter, when seabird abundance was highest, the area of highest density containing between 1000--1800 os./km2 covered the western and central parts of the study area (see Figure 4 in Appendix I.2 of the Report). In the spring, after a decline in bird numbers, their preference for two areas located in the eastern and northwestern parts of the basin became apparent (see Figure 5 in Appendix I.2 of the Report). However, the average density at the sites of the most abundant concentrations of avifauna slightly exceeded 100 os./km2.

In 2016/2017, for the environmental impact assessment of the Baltic offshore wind farm, seabird surveys were carried out on Slupsk Shoal in parallel with the studies in the farm area. During all the research cruises, the presence of 18 species of birds was found, including 12 species associated with the marine environment (in order from highest to lowest abundance: long-tailed duck, uhla, silvery gull, guillemot, alka, scoters, black-throated duck, lesser black-backed gull, yellow-legged gull, saddle-backed gull and red-throated duck) and 6 species of waterbirds rarely found at sea away from the coast (gray gull - 8 os, mute swan, cormorant and white-fronted goose - 4 individuals each, gannet - 2 individuals and marmot - 1 individual). The total abundance of all birds observed on the water along transects on Slupsk Shoal was 58,011 individuals. The long-tailed duck was by far the dominant species accounting for as much as 93% of all birds found. The threshold of 5% participation in the grouping was still reached by the uhla, and the remaining species appeared in low numbers. During the periods of spring and autumn migration, the maximum densities of avifauna in the area of Slupsk Shoal reached up to 500 os./km2. During the summer, bird abundance in the area in question was very low, and densities of 0.1 to 1 per square kilometer predominated. In contrast, in winter, densities of more than 10 wasps/km2 predominated, and in about 1/5 of its area they exceeded 100 wasps/km2, locally reaching values of more than 500 wasps/km2 (IMG Consortium and MEWO et al. 2017).

A seabird survey of Slupsk Shoal was also conducted in 2017-2018 for the FEW Baltic II environmental impact assessment. During the survey, 14 species of seabirds were found there (in order from highest to lowest abundance: : long-tailed duck, uhla, silvery gull, alka, scoter, black-throated diver, yellow-

legged gull, guillemot, little gull, red-throated diver, saddleback gull, eider, glacier gull), 24 species of waterbirds, rarely found from a great distance from the coast (gray gull, bean goose, mallard, marmot, mute swan, cormorant, barnacle, lapwing, laughing stock, goose, partridge, canadian barnacle, merganser, common tern, roseate, gray heron, black tern, white heron, dabbling heron, whooper swan, golden plover, great grebe, screech-owl) and 15 species of terrestrial birds (lark, gray wagtail, starling, siskin, swift, swallow, springtail, redshank, woodpigeon, woodpigeon, chaffinch, yellow wagtail, myotis, reed warbler, gray flycatcher, shorebird).

On Slupsk Shoal during the survey, the total number of stationary birds observed was 8555 (average 71.4 os/h). Here, the long-tailed duck was also the dominant species among all birds (Baltic Trade and Invest Ltd., 2019).

Slupsk Shoal, as one of three Natura 2000 areas located in Polish marine areas established for the protection of wintering birds, was included in the Monitoring of Wintering Seabirds started in 2010 under the PMŚ. During the 2020 count on Slupsk Shoal, the long-tailed duck was the most abundant species here, clearly more numerous than the uhla (Table 1). Slupsk Shoal was and still is one of the most important long-tailed duck wintering grounds in the Baltic. The number of uhla has gradually increased here in recent years. During the counts carried out as part of the Monitoring of Wintering Seabirds in 2011 and 2012, only 72 and 31 individuals of the species were observed there in the transect belt, while in the last three years there were already 1,317, 167 and 271 individuals.

Table 1. Abundance and density and frequency indices of individual species recorded within transects and snap-shot counts, as well as all individuals seen during the 2020 count on Slupsk Shoal. Core species for the monitoring program are shown in bold (GIOS 2021)

Species	Individuals in transect	Density [s./km2]	All observed individuals	Frequency rate [person/hour of cruise]
Long-tailed duck	1625	32.5	2741	502.9
Uhla	271	5.4	498	91.4
Silver gull	11	0.2	84	15.4

Nurzyk			2	0.4
Goose			2	0.4
Red-throated diver			1	0.2
Saddleback gull			1	0.2
Individuals not marked as to species				

Species	Individuals in transect	Density [s./km²]	All observed individuals	Frequency rate [person/hour of cruise]
Alka unmarked	1	+	5	0.9
TOTAL	1923	38.4	3400	624.0

The long-tailed duck was by far the most abundant species recorded during monitoring on Slupsk Shoal in 2020, accounting for about 81% of all individuals observed. The second most abundant species was the uhla, with about 15% of the total grouping. The remaining species were far less abundant and the share of none of them exceeded 2.5%. During the entire cruise, only 5 individuals of the long-tailed duck (one of the three protected species in the area, along with the long-tailed duck and uhla) were observed.

In 2020, high densities of long-tailed duck were recorded on Slupsk Shoal, in excess of 50 os./km², but only in the eastern part of the basin. In the case of the uhla, the maximum density exceeded 10 os./km². Compared to the years 2011-2014, when the sea urchin was encountered sparsely on Slupsk Shoal, there is an increase in the number of birds of this species on this body of water (GIOŚ 2021).

Considering the changes in the density index of long-tailed duck and sculpin on Slupsk Shoal from 2011 to 2018 (see Figure 9), attention is drawn to the very large fluctuations in the abundance of long-tailed duck. This most likely indicates the birds' movements between Baltic wintering grounds. Significant fluctuations in abundance have also been observed for uhla. The results of the monitoring indicate that Slupsk Shoal is a body of water of increasing importance for wintering uhla, where an increase in the number of birds of this species is marked.

[os.km²]	[os./km²]
Lodówka	Long-tailed duck
Uhla	Uhla

4. Summary

Outside the coastal zone (up to 1 km from the shoreline), most birds congregate in bodies of water less than 30 m deep, while in the zone with a depth of more than 40 m, bird counts are very low, usually

well below 1 os./km^2. Only during the fishing season, large concentrations of gulls can be found in the fishing area (Meissner 2011).

Although long-tailed duck, scoters and scoters can dive to great depths (long-tailed duck up to 60 meters) in search of food, they prefer shallower waters where food acquisition is easier. Outside the coastal belt, these species in the Baltic are most abundant in the zone of waters up to 30 meters deep. Ichthyophages, which include divers, grebes and auks, can follow schools of fish, so the locations of their higher concentrations can change. Surveys conducted in the Baltic in winter have shown that both species of divers and guillemots reside most often in bodies of water that are no more than 30 meters deep, while the nuit and alka appear most abundantly

in a zone with depths of 30 to 50 m (Meissner 2011).

Taking into account the above and the results of the research described in points 2 and 3 of the section, it can be concluded that the area of the planned OWF BIII does not constitute a body of water particularly important for seabirds

in any of the analyzed periods. However, the significant densities of avifauna found during the survey in the Slupsk Shoal area during migration and wintering, as well as at the very boundary of the shoal in the area designated for the Baltic offshore wind farm during wintering, confirm the importance of the shoal area as a feeding and resting place for seabirds.

Birds Directive	Directive 2009/147/EC of the European Parliament and of the Council of 30 November 2009 on the conservation of wild birds (Official Journal. EU L 20/7, 26.01.2010, p. 7-25, as amended)
OWF BIII / Project	Bałtyk Środkowy III Offshore Wind Farm
IMF Baltica	Baltica offshore wind farm
Baltic Power OWF	Baltic Power offshore wind farm

1. Introduction

This section presents the characteristics of seasonal bird migrations over the area of the planned OWF BIII, developed mainly on the basis of the results of surveys conducted in the area. A report with the results of the migratory bird surveys along with a description of the methodology used is attached as Appendix J to the Report.

In addition, the results of observations of migratory birds carried out in bodies of water adjacent to the BIII offshore wind farm area, carried out for the environmental impact assessment of the Baltica offshore wind farm and the Baltic Power offshore wind farm, were taken into account.

2. Characteristics of seasonal bird migrations over the OWF area BIII

Surveys of migratory birds were performed during the spring and fall migration periods.

Surveys were conducted from a boat anchored at a specific location located in the center of the study area.

The monitoring program included four types of surveys to obtain complementary information on various aspects of bird migration:

- daytime visual observations of birds,
- tracking migratory birds using horizontal radar during daylight hours,
- recording the flight altitude of migratory birds using vertical radar during nighttime hours,
- acoustic observations of migratory birds during nighttime hours.

The monitoring of migratory birds in the BIII offshore wind farm area made it possible to characterize seasonal bird migrations over the study area.

A high species diversity of migratory birds was noted.

During the spring migration period, 97 species were tagged, including 32 waterbirds and 65 landbirds, while 56 species were tagged during the fall migration period, including 25 waterbirds and 31 landbirds. The species composition found during the survey included almost all seabird species found in the Baltic Sea region and all major taxonomic groups of birds associated with the land environment. Summaries of bird species found during the spring and fall migration periods, respectively, with an indication of the number of individuals recorded for each of the survey methods used are presented in Table 5.32 and Table 5.33 in Appendix J of the Report.

The group of birds migrating over the area of the planned OWF BIII during the daytime was dominated by long-tailed ducks, particularly long-tailed ducks, scoters and scoters.

In terms of the biogeographic size of the seabird population, the largest percentage was recorded for the scoter (3.4%). Since scoters also migrate at night, the total percentage of this species is most likely higher, reaching 10%. Sea ducks migrating over the OWF BIII area do not fly over it in clusters but in a dispersed manner.

During the autumn period, among the species migrating over the area of the planned farm, geese were recorded in the greatest numbers. Their total estimated number was 100,000 individuals, accounting for 4% of the total goose species population.

Other duck species identified during the survey, ducks proper and ruddy ducks, did not occur in large

numbers over the BSIII offshore wind farm area, only occasional small flocks of them were recorded during both spring and autumn migrations.

The presence of two species of divers (black-throated diver and red-throated diver) was recorded during the survey, however, in relatively low numbers. It is estimated that about a few hundred birds of these species fly over the BSIII area during the migration season, which is only a small percentage of the biogeographic population of these bird species. Burrows migrate both along the coastline and over the open sea area in a highly dispersed manner.

The presence of all 3 species of the alk family (Alcidae) inhabiting the Baltic Sea region has been recorded: alka, nuisance, guillemot. Of these, alka was the most abundant species. Based on the results obtained, it is estimated that more than 6,000 auks may fly over the area of the planned OWF BIII, with the number of migrating birds most likely overestimated due to the local flights of birds living in the area, which is also indicated by data on the direction of bird flights.

Gulls did not occur in large numbers during migration periods in the BIII OWF area, with the Lesser Black-backed Gull (an EU Bird Directive Annex I species) being systematically observed during both spring and autumn migrations. Estimates indicate that up to about 1,500 birds of this species (or 2% of the biogeographic population) may fly over the BIII OWF area during the migration period.

Cormorants were regularly observed in the BIII OWF area during the survey, but not in large numbers. Calculations indicate that about 1,000 individuals of this species may fly over the BIII OWF area during the migration period. While some of the birds observed during the survey may have been migratory birds over the BIII OWF area, many of the cormorants observed did not show a consistent direction of flight, suggesting that they were resident birds that had ventured too far into the open sea.

During the survey, quite a number of cranes were found flying over the area of the planned farm during the autumn migration period - a total of 1,483 individuals of this species were recorded during visual observations during this period.

With regard to plovers, the largest percentage of biogeographic population size was recorded for the golden plover (3.7%). With the exception of the golden plover, they did not occur in large numbers during surveys in the BIII OWF area during migration periods. As for the golden plover - several large flocks were recorded in the spring.

During the survey of the area of the planned farm, only a few raptors were recorded: 8 birds of different species in spring and 1 unmarked falcon in autumn. Birds of prey, which use rising thermal air currents during flight, are reluctant to choose areas of open water for their flight route, where there are not sufficiently strong thermal currents used by them for rising flight. Therefore, only occasional overflight of raptors is expected over the BIII OWF area - their regular migration is not expected.

Although many of the passerine birds that migrate during the day avoid flying over the open sea, surveys of the area of the planned farm recorded the presence of some species belonging to this order in large numbers, albeit representing a small part of their very numerous populations. The most frequently observed species were chaffinch, starling, lark, gray wagtail and rich-eyed warbler. Most passerine birds migrate at night dispersing at high altitudes.

The information on flight directions collected during the survey clearly indicates that the overwhelming number of birds observed over the BIII offshore wind farm area are seasonally migratory species, maintaining a constant direction of flight to the northeast during spring and southwest during autumn. However, among some bird species, the dominant direction of flight was not clearly recorded at certain times, indicating that these were most likely resident individuals in the study area. The group included alcids and cormorants and, in early spring, long-tailed ducks.

Most of the waterbirds recorded during the survey were flying during the day low over the BIII OWF

area, below the potential height of the wind turbine rotor (<20m). Among marine species, only in the case of divers and cormorants did a relatively large proportion of recorded individuals (about 30%) fly at heights above 20 meters above sea level. A large proportion of birds associated with the terrestrial environment migrating over the BIII offshore wind farm area during the day flew at undersized heights, with a significant proportion of migrating geese, cranes and plovers flying at wind turbine rotor placement heights above 200 meters.

In the case of nocturnal migrants, the vast majority of birds flew over the BIII OWF area at heights above 200 meters above sea level. The highest number of nighttime birds was recorded at heights of 400-600 meters, indicating significantly higher flight altitudes compared to migrations taking place during daytime hours.

Based on the results of the survey, it was concluded that the area of the planned location of OWF BIII does not lie on the main migration route, through which birds fly in large concentrations during seasonal migrations. However, birds of various species fly over the area, migrating in a dispersed manner over marine areas.

Taking into account the abundance of bird species determined during surveys within the farm area, their conservation status, and their sensitivity to the impacts of offshore wind farms, the following species/species groups were included in the assessment of the impact of OWF BIII on migratory birds: auks, guillemots, long-tailed ducks, scoters, murres, marmots, geese, swans, cormorants, golden plovers, little gulls, blacksmiths, cranes, and woodpigeons.

In the spring and autumn of 2016 and March 2017, migratory bird surveys were conducted in the Baltica offshore wind farm area, adjacent to the north and northwest of the Project area. During the survey, data were collected at three survey stations using horizontal and vertical radar, visual observations and acoustic recordings (IMG Consortium and MEWO et al. 2017).

In all survey seasons, 57,112 birds belonging to 145 species were recorded (visual observations and acoustic recordings) in the Baltica OWF Area, of which 126 were recorded during visual observations (the urban pigeon was excluded from the analyses, as a domesticated species), and 48 were identified on acoustic recordings (ibid.).

The detailed analyses in the assessment of the impact of the Baltic offshore wind farm on migratory birds did not include species that were irregularly and infrequently recorded in its area, i.e., whose number of observations does not exceed 30 individuals (10 per research station), and species that were recorded in numbers between 30 and 50 individuals, but observed in several flocks (1-5). Of all the migratory bird species/groups identified during the survey, the detailed analyses in the report included: long-tailed duck, scoter, scoter, marmot, mallard, red-breasted goose, geese (white-fronted goose, goosander and bean goose), swans (black-tailed swan, whooper swan and mute swan), divers (black-throated diver and red-throated diver), alcids (alka and dipper), cormorant, lesser black-backed gull, laughing gull, yellow-legged gull, gray gull, terns (black tern, little tern, arctic tern, common tern and Caspian tern), sharp-tailed otter, great curlew, piping plovers (golden plover and gray plover) and crane (ibid).

Based on visual observations, it was found that more than 92% of all birds observed in the Baltic Sea Area in the spring of 2016 were flying at heights of 30 meters or less. At the time of the autumn survey, it was 86.1% of birds, while in March 2017. - 95,6%. Most of the sea ducks and alcids observed during the survey flew below 20 meters above sea level. Gulls and swans were observed at higher altitudes, but still dominated at elevations of up to 20 meters above sea level (ibid).

The predominant direction of flight of birds migrating through the Baltica IMF Area in the spring season was northeast-east, and in the autumn season was southwest-west. In March 2017, some of the birds headed in different directions than expected, which is related to the fact that the observations included

birds that had not yet started their spring migration and were still within the wintering grounds near the IMF Baltica Area, making short flights, moving in search of food, for example. They may also have been partly local birds that nest along the Polish Baltic coast (ibid).

The general flight directions of all birds found during surveys conducted during the spring and autumn migration periods in 2013 in the BIII offshore wind farm area and in 2016 in the body of water adjacent to the area of the planned farm designated for the Baltica offshore wind farm were consistent with each other. The aforementioned directions are shown in Figure 1.

Figure 1. General flight directions of all birds during spring and autumn migration periods recorded during surveys conducted in the BIII offshore wind farm area in spring (A) and autumn (B) 2013, and during surveys conducted in the Baltica offshore wind farm area in spring (C) and autumn (D) 2016. (Appendix H of the Report; IMG and MEWO Consortium et al. 2017; Baltic Trade and Invest Sp. z o.o., 2019)

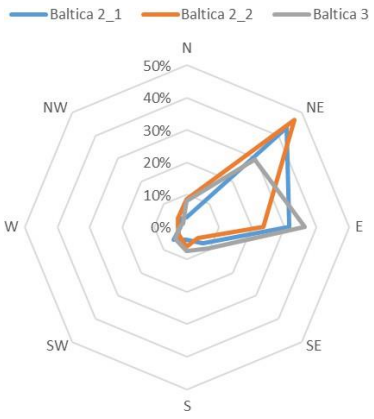
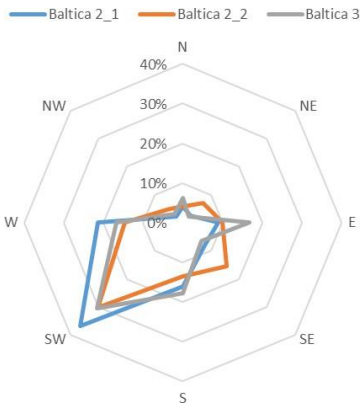
C



D



During visual observations conducted in the BIII OWF area in 2013, a greater number of bird species were determined than during analogous observations conducted at the Baltica_3 station located in the Baltica OWF area in 2016, in the general direction of bird migration over the areas in question. In the group of waterbirds during visual observations over the BIII OWF area, the most numerous (above 100 individuals) were recorded (in order from the largest to the smallest number of individuals observed): scoter, long-tailed duck, uhla, marmot, cormorant and alka, while at the Baltica_3 station: scoter, scoter,

uhla, marmot, alka, cormorant, yellow-legged gull, little gull and mallard. During the surveys conducted at the Baltica_3 station, there were no numerous flights of cranes during the fall migration period as were recorded over the BIII OWF area in 2013. Considering the flight directions of cranes during the fall migration period found during the surveys in the BIII OWF area (see Figure 5.100 in Appendix J to the Report), it can be suspected that a fairly numerous flight of this species also took place over the Baltica_3 OWF Baltica Area. On the other hand, the results from the Baltica_3 station do not indicate the occurrence of crane migration over the Baltica 3 Area in the fall of 2016. (not a single individual of this species was recorded during visual observations). This may indicate significant variability in the intensity of the crane migration phenomenon over the analyzed body of water, including the area of the planned OWF BIII.

Another survey of migratory birds was conducted in 2018-2019 in the area designated for the construction of the Baltic Power offshore wind farm. At the time, 95 species of birds were observed. Long-tailed duck and long-tailed duck (IMUMG Consortium and MEWO et al. 2020) were the most abundantly represented, as in the BIII and Baltic OWF areas.

1. Introduction

Marine mammals are among the species that may prove most sensitive to disturbance from offshore wind farm construction and operation. There are four species of marine mammals in the Polish Baltic Sea - the harbor porpoise (Phocoeana phocoena), the gray seal[1] (Halichoerus grypus), the common seal (Phoca vitulina) and the ringed seal (Pusa hispida). The construction as well as operation of an offshore wind farm may have a negative impact on them. Therefore, it was necessary to determine whether the planned location of the OWF is a region of high importance for these marine mammals.

This chapter presents a characterization of the occurrence of marine mammals in the area of OWF BIII. For the purpose of its development, the results of marine mammal monitoring conducted in the area of the planned farm and in its vicinity in 2012-2013 by DHI were used. A report with the results of this monitoring, along with a description of the methodology used, is attached as Appendix K to the Report.

The chapter also refers to the results of marine mammal monitoring carried out in waters adjacent to the BIII offshore wind farm area for the environmental impact assessment of the Baltic offshore wind farm, as well as the results of harbor porpoise monitoring carried out as part of the State Environmental Monitoring and the SAMBAH project.

2. Characteristics of the occurrence of marine mammals in the OWF area BIII

Monitoring of marine mammals was carried out using acoustic and visual means. Acoustic monitoring was dedicated to porpoises, and was performed using passive C-POD porpoise detectors. To verify the results obtained in acoustic monitoring, porpoise detections are confirmed visually by qualified personnel.

Visual monitoring, which is currently the only method of estimating the species' density and abundance on a large scale, was conducted from the air. Aerial observations were made in a much larger area, covering, apart from the BIII OWF area, the area of Slupsk Shoal (partially) and the neighboring areas intended for the construction of offshore wind farms, including the areas of the Baltic II and Baltica OWFs, as well as the area of the Polenergia Baltic I OWF located adjacent to the Central Shoal. The locations of C-POD detectors and aerial observation transects during marine mammal surveys are shown in Figure 16 and Figure 22 in Appendix L of the Report, respectively.

All large-scale studies of the presence of porpoises in the Baltic Sea carried out to date indicate a clear seasonality in their occurrence - the highest number of individuals was recorded in summer, with smaller numbers in winter and early spring. Accordingly, it was decided to conduct aerial monitoring mainly during spring and summer. Two follow-up surveys were also conducted in the fall, while no surveys were conducted in the winter.

Monitoring conducted in the area of OWF BIII showed the presence of three species of marine mammals in the area of the planned wind farm and adjacent waters: harbor porpoise (Phocoena phocoena), gray seal (Halichoerus grypus) and common seal (Phoca vitulina). The activity of all the above-mentioned animal species was very low. Passive acoustic monitoring showed only 5 days of porpoise presence per year. A total of nine individuals of marine mammals were observed during aerial visual monitoring, Of which five were porpoises and four were seals. One of the seals was a grey seal, two were common seals,

[1] According to the "Polish Nomenclature of Mammals of the World" of the Museum and Institute of the Polish Academy of Sciences, the current Polish species name is the sea grebe

and in the case of one individual, the species could not be determined. All the animals were adults, and no juveniles were observed.

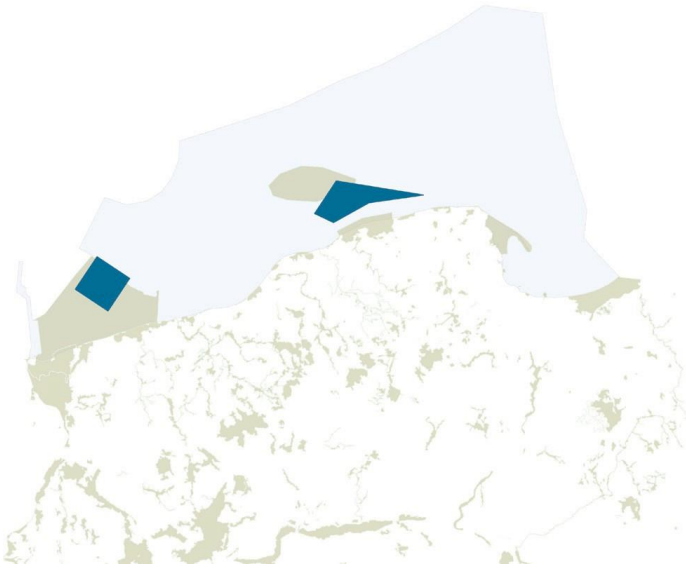
Based on the results, it was concluded that the BIII offshore wind farm area is characterized by very low activity of marine mammals. Due to the small number of days on which the animals were found, it was not possible to determine seasonal trends in their occurrence. The lack of juvenile porpoises means that the study area is not relevant to the reproduction of these animals. It was concluded that the BIII OWF area could be a region for porpoises to obtain food.

In the period from March 2016 to April 2017, marine mammal surveys were conducted in the body of water encompassing the Baltica offshore wind farm area, adjacent to the area of the planned BIII offshore wind farm to the north and northwest, by recording the presence of porpoises using C-POD acoustic equipment and aerial observations. Similarly to the marine mammal surveys performed in the BIII offshore wind farm area, C-POD recorders were deployed within or adjacent to the Baltica offshore wind farm area, while aerial observations covered a larger body of water, including the BIII offshore wind farm area (IMG Consortium and MEWO et al. 2017).

The results obtained from the aforementioned study show that porpoise detections in the area are relatively few. The clicks were recorded at three research stations between June and August 2016. (54 detections). The highest number of detections (98 detections) was recorded at one research station between August and November 2016. Porpoise detections also took place at several other stations between January and March 2017. (22 detections), 3 detections were also recorded at one research station between March and April 2017. However, it should be noted that more porpoise detections were recorded in summer than in other seasons. No porpoises were observed during aerial observations, despite good observation conditions. However, during the flights it was possible to observe closer unidentified seals: in May 2016. (1 individual), June 2016. (2 individuals) and in April 2017. (1 individual). The results collected indicate that the study area is an area with a low density of marine mammals (ibid).

In 2016-2018, in connection with the implementation of the PMŚ project entitled. "Pilot Implementation of Monitoring of Marine Species and Habitats in 2015-2018," surveys for porpoises were conducted in the Pomeranian Bay and Stilo Shoal (located southeast of the planned OWF BII). The location of the sites where porpoise monitoring was performed during the aforementioned period is shown in Figure 1. Seal surveys within the framework of the aforementioned project were conducted along the entire coast, so at a relatively considerable distance and under conditions significantly different from the BII OWF area.

Figure 1. Location of porpoise monitoring sites in 2016-2018 within the framework of PMŚ (Baranska et al. 2018)



Analysis of the collected data showed significant differences in porpoise occurrence between the areas - the Pomeranian Bay site had ten times as many days of positive detections (an average of 4.56 DPD) as the Stilo Shoal site, located in the area of OWF BIII (an average of 0.32 DPD). At the same time, it has been shown that the presence of porpoises in both areas is characterized by seasonality - in the Pomeranian Bay the maximum DPD values were recorded in the summer months, while on Stilo Shoal in the spring (Malinga M. et al 2019[2]). According to the released data of the Environmental Protection Inspectorate obtained within the framework of the State Environmental Monitoring, during the entire period of the aforementioned monitoring, i.e. from March 2016 to August 2017, 3 to 5 days of positive detections of harbor porpoise were found at each of the five CPOD stations located on Stilo Shoal (CPOD06-CPOD10) (GIOŚ 2019[3]).

Data on the occurrence and distribution of porpoises and their abundance in the Baltic Sea also come from the comprehensive acoustic monitoring of the species carried out in 2011- 2013 as part of the SAMBAH project. Monitoring results indicate that the porpoise population in the northeastern Baltic has an estimated 497 individuals (this value is believed to represent the population size of the Baltic proper), and in the southwestern part an estimated 21,390 individuals. During the summer season (May to October), detections were concentrated in two areas: one located in the southwestern part of the Baltic Sea and the other located on and around offshore shoals in the central part of the Baltic proper, while during the winter season (November to April) they were more dispersed. The identification of two areas with higher concentrations of summer porpoise detections based on the results of the SAMBAH project, combined with information from Danish satellite surveys of harbor porpoises from the Belts Sea population, led to the division of the study area into two areas of summer porpoise populations. The Belts Sea population is believed to dominate the southwestern part, while the Baltic proper population is mainly found in the northeastern part. During the winter season, the areas of occurrence of the two populations appeared to overlap (SAMBAH 2016).

Results from the SAMBAH project indicate that during the summer season there was a high probability of

[2] As the methodology does not specify the date of its development/publication, the date of access is given.

[3] Since the data made available is not dated, the date the data was made available is given.

porpoise detections on and around the submarine shoals south of Gotland and east of Öland. The aggregation of animals in the area was most evident in the period through May to August, the breeding season. This is also the period when their separation from the population concentrated in the southwest of the study area, between Denmark, Germany and Sweden, was most pronounced. During winter, especially in January-March, the animals were more dispersed, with intermediate detection probabilities occurring along the coasts of Poland and the Baltics, along the east coast of Sweden and in Finnish waters (SAMBAH 2016).

Determined from the results of the SAMBAH project, the spatial distribution of the probability of porpoise detection in the study area by month is shown in Figure 2.

Figure 2. SAMBAH project results - spatial distribution of probability of porpoise detection in the study area by month (red color indicates the highest probability of porpoise detection, while dark blue - the lowest) (GDOŚ 2015)

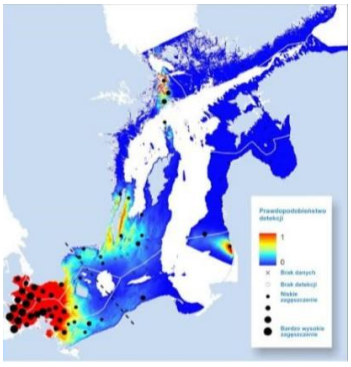
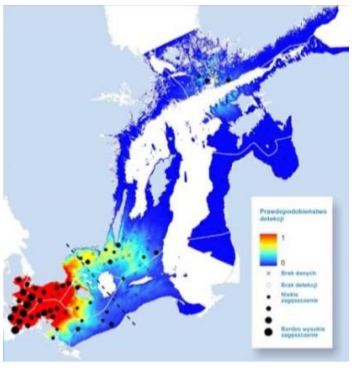
November



December

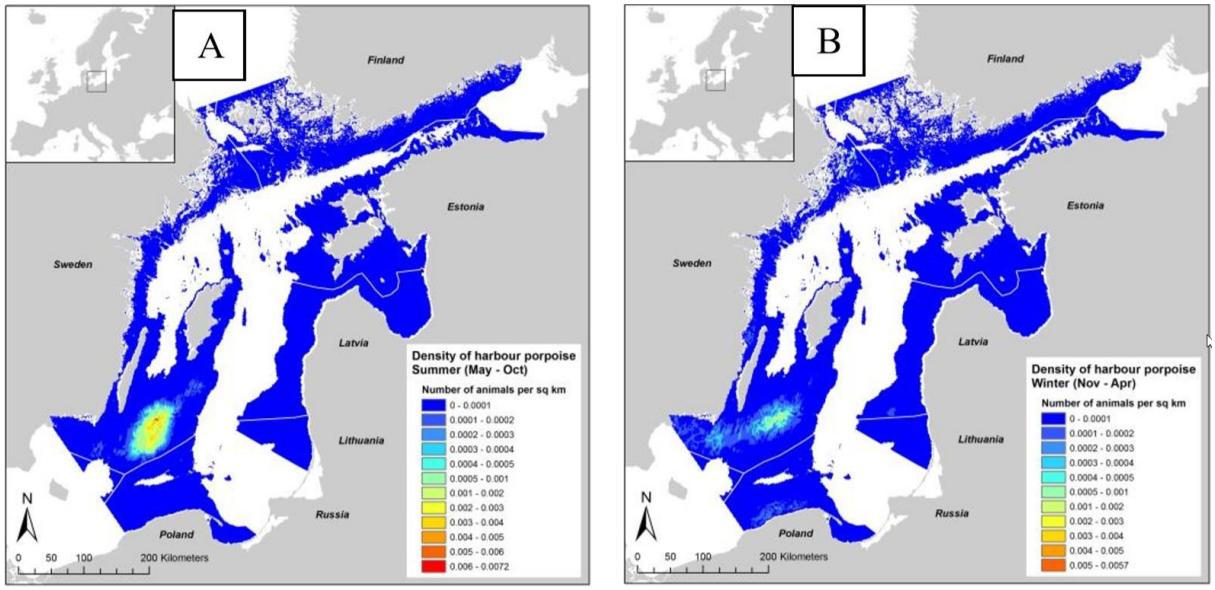


Prawdopodobieństwo detekcji	Probability of detection
Brak danych	No data available
Brak detekcji	No detection

Niskie zagęszczenie	Low density
Bardzo wysokie zagęszczenie	Very high density

According to the results of the SAMBAH project, the highest probability of porpoise detection in the BIII offshore wind farm area is in April. It is worth mentioning that the maximum values of DPD were recorded during porpoise monitoring conducted in 2016-2018 within the framework of the PMŚ at the Stilo Shoal site (see Figure 1), located south of the area of the planned farm, just in the spring period. As part of the SAMBAH project, maps of predicted summer and winter harbor porpoise densities were developed for the entire study area. Figure 3 shows maps of porpoise densities for the northwestern part of the study area, within which OWF BIII is planned.

Figure 3. Predicted densities of harbor porpoise (number of individuals per$_{km2}$) during the summer season - May to October (A) and winter season - November to April (B) in the northwestern part of the SAMBAH study area (SAMBAH 2016)



According to the results of the SAMBAH project, the BIII offshore wind farm region is an area with low predicted densities of porpoises, with densities slightly higher between November and April.

Taking into account all the above-described results of marine mammal surveys, it can be concluded that the region of the planned farm is not an area intensively used by this group of animals. The area is also not, as the results of the SAMBAH program indicate, a region of importance for the ecology and biology of any of the isolated populations of Baltic harbor porpoise. It can only represent an area of movement of individual individuals or periodic feeding grounds. However, due to the relatively low value of fish stocks, which are the main food of porpoises, it is not a feeding area of significant importance.

OWF BIII / Project	Bałtyk Środkowy III Offshore Wind Farm
IMF Baltica	Baltica offshore wind farm
Baltic Power OWF	Baltic Power offshore wind farm

1. Introduction

This section presents the characteristics of the occurrence of bats over the area of the planned OWF BIII and in its vicinity during spring and autumn migration periods. This characterization was prepared on the basis of the results of bat monitoring conducted in the basin covering the area of OWF BIII with the buffer zone in 2013. The report with the results of the chiropterological monitoring along with a description of the methodology used is attached as Appendix L to the Report.

In addition, the section presents the results of bat activity monitoring carried out in areas adjacent to the BIII offshore wind farm area for the environmental impact assessment of the Baltica offshore wind farm and the Baltic Power offshore wind farm.

2. Characteristics of the occurrence of bats in the area of the OWF BIII

Twenty-two inspections (out of 25 planned) were carried out during the one-year period covering spring migration (April-May) and fall migration (August-September). The control consisted of monitoring cruises along a transect and listening at two listening points rotated during the surveys.

A total of 13 bat sounds were recorded in the area of the OWF and the buffer zone. Signals were found in the northeastern part of the study area. They were recorded during two monitoring cruises 11 and 12, during the spring migration period under suitable weather conditions. Four signals were recorded on the transect, and 9 were recorded while conducting listening sessions at listening point No. A. As a result of the analysis involving data extraction and transformation of the recorded signals, it was concluded that the collected sounds emitted by bats belong to a species of the gloomy bat family - the great boa constrictor. It is one of the largest bats in Poland, with a European distribution range from the Iberian Peninsula in the west to the Urals and Caucasus in the east. Its natural habitat is forested areas, but it is also observed in built-up areas. It is a species that migrates long-distance up to 1,600 km between summer (northeastern Europe) and winter (southwestern Europe) locations. It is seen during migration over the open sea.

Taking into account the number of recorded signals emitted by the Great Boer in the area of the Baltic Sea III offshore wind farm, an index of the activity of this species in the study area was calculated for the measurement period - spring migration, as well as for individual monitoring trips, during which the sounds of the Boer were recorded. The obtained values were compared with the adopted reference scale of bat activity, which was based on results from pre-investment surveys of planned onshore wind farms across Poland. The activity of the Great Boer ranked in the low activity range. Activity at this level does not require the need for preventive and mitigation measures.

The number of individuals observed does not clearly indicate the existence of a permanent migration corridor for this species in the BIII OWF area. In terms of wildlife, it can be concluded from the studies that the area of the planned Baltic III offshore wind farm is not a valuable region for bats.

Surveys of bat activity in the Baltica offshore wind farm area, adjacent to the BIII offshore wind farm area to the north and northwest, were carried out during the spring migration period (May 2016, April-May 2017) and the fall migration period (August-September 2016). A total of 79 records were recorded that showed evidence of bat activity. The records were attributed to the following species:

the great boar, greater carlik, lesser carlik and woodrat, and the red-legged nightjar. The Great Boer and Forest Boer have been recorded during the autumn migration period. The greater carnivore and the lesser carnivore were recorded during both spring and autumn migrations, while the red-legged nightjar was found once during spring migration. During the bat activity surveys, mainly low activity and a single moderate activity were recorded. The activity index for individual species for the entire spring and autumn migration period indicates low bat activity in the Baltic offshore wind farm study area (IMG Consortium and MEWO et al. 2017).

Of the listening points designated for bat activity surveys in the Baltica offshore wind farm area, the closest to the area of the planned BIII offshore wind farm were points P_N02 (to the north--west) and P_N03 (to the north). At the first of the aforementioned listening posts, no bat activity was recorded during all three inspections. On the other hand, during two of the three inspections carried out, greater carlik activity was found (low in May 2016 and moderate in May 2017). During the fall migration period at listening point P_N02, during an inspection conducted in August 2016. (one of two) recorded low activity of two bat species - the great bole and greater carnifex. However, at listening point P_N03, low activity of two other species - the lesser spotted carlik (in August 2016) and the woodrat (in August and September 2016) - was observed during fall migration*(ibid*).

In 2019, surveys were conducted at the Baltic Power offshore wind farm area adjacent to the BIII offshore wind farm to the east. Surveys during the spring migration period were carried out in April and May, while fall migration was carried out from August to October. A total of 83 records (11 in spring, 72 in autumn) were recorded, which showed evidence of bat activity. The records were assigned to the following species: greater carlik, lesser carlik, and great bole (for some of the signals it was not possible to assign to a specific species) (IMUMG Consortium and MEWO et al. 2020).

Previous surveys of the occurrence and timing of bat activity in the Baltic Sea and southeastern North Sea coasts and islands, conducted at 19 locations between 2007 and 2009, indicate that for the most part, migratory bats in the Baltic move in dispersal (broad front) (Rydell 2014). Thus, it cannot be ruled out that migratory flights of some of the listed bat species may occur over the BIII OWF area or in its vicinity at different times. The monitoring results presented above, however, indicate that bats are not active over the BIII offshore wind farm and in the area during seasonal migration periods and confirm the absence of significant bat migration corridors (flight concentrations) over the analyzed basin.

PWKZ	Pomeranian Regional Conservator of Monuments

1. Introduction

This section presents a characterization of the cultural heritage found in the area of the planned BIII OWF and in its potential impact zone. The characterization in question was developed primarily on the basis of the results of archaeological surveys conducted in 2013-2014 by the Maritime Institute (see Appendix M to the Report).

Data on known objects in the Database of Underwater Objects (BDOP) of the Navy Hydrographic Office were also obtained for the development of this section.

2. Characteristics of cultural heritage in the offshore wind farm area BIII

The research involved analysis of archival materials, analysis of sonar data. Verification of objects was also carried out using an ROV underwater inspection vehicle. In addition, based on the data provided by the Maritime Institute on seismoacoustic surveys and the results of the analysis of geological survey material (core analysis), the possibility of the presence of remnants of human activity related to the Stone Age was determined.

Data on marine archaeological sites in waters adjacent to the Pomeranian Voivodeship are collected primarily by the National Maritime Museum[1] (NMM) in Gdansk in the Evidence of Underwater Archaeological Sites (EPSA). The data is submitted to the BHMW and the Pomeranian Regional Monument Conservator. The most valuable finds have also been registered in the AZP system since this year. The archives of the NMM and BHMW did not contain any information on heritage remains in the study area.

In accordance with the assumptions contained in the methodology, searches were carried out to capture the remains of Stone Age settlements using seismoacoustic, geological and ROV inspection methods.

Analysis of archival materials in the direction of the search for the remains of prehistoric settlements and wrecks of historic transport units did not detect any information on the remains of cultural heritage in the study area. An archival search for transport vessel disasters found information about the disappearance in the study area of 84 ships built between the 16th and late 18th centuries. This information was not confirmed during the field survey.

As a result of the operations, one shipwreck was discovered. The wreck is tentatively dated to the early 20th century. This is evidenced by both the steam propulsion system and the mixed steel and wood plating. The wreck is not of high historical value and can be made available for tourist diving. The site is listed in the EPSA Record of Underwater Archaeological Sites under the symbol B96.1 and has been granted a KEZA card.

During the analysis of the geological survey material, no archaeological relics were found in the shallow cores.

At the time of the survey, no relics of areas that potentially could have been in the zone of settlement influence were observed. No archaeologically valuable objects have also been found at the bottom of the OWF BIII area.

1. Introduction

This chapter presents the characteristics of fisheries in the area of the planned BIII OWF and in its vicinity. This characterization was developed primarily based on data from fishing vessel catch reports submitted to the Fisheries Monitoring Center taking into account fish species, month of catch and vessel size (vessels up to 12 meters and over 12 meters)[1]. The scope of the analyzed data covers the years 2015- 2020.

An analysis of changes in the volume[2] and value[3] of catches and fishing effort (number of fishing days[4] and number of Polish fishing vessels[5] involved in 2015-2020 in the area of the planned investment) was conducted. An analysis of the seasonality of fishing by month of the year was conducted.

Since data on fishing fleet activity, in the most detailed terms, is available for the areas of the Baltic squares (the area of a single square is about 400 square kilometers), the data compiled refers to the area of entire squares. Due to the nature of fish stocks, which both in terms of time and distribution are dynamic in nature, analyzing them in a very small area is not substantively justified. The analysis includes the area of squares N7, N8, M7, M8, within which the BIII OWF is located.

In order to determine (quantify) with as much accuracy as possible the impact of the investment on fisheries (determine potential losses of fisheries) in the area occupied by the BIII OWF (in the case of complete exclusion of the farm area from the possibility of fishing), the relative share of the area that the farm will occupy to the total area of fishing squares was taken into account. The area of OWF BIII is about 117 square kilometers, while the area of fishing squares N7, N8, M7, M8 is 1.58 thousand square kilometers. Thus, IMF BIII occupies about 7.4% of the squares.

A general characterization of the ichthyofauna occurring in the area of the planned OWF BIII and in its vicinity is provided in Chapter 7 of Volume III of the Report. Meanwhile, the results of surveys and analyses of ichthyofauna carried out in 2009-2013 by the Maritime Institute of Fisheries - National Research Institute in the area of OWF BIII, along with a description of the survey area, its scope and methodology used, are attached as Appendix H to the Report.

2. Legal conditions for the operation of the sector fisheries

At the global level, the most important operating framework document for fisheries is the Code of Responsible Fisheries[6], which sets out principles and standards for the conservation, management and development of all fisheries.

The overarching document in the European Union is the Treaty on the Functioning of the European Union[7]. It provides for exclusive or shared competence in a specific area. Setting fishing quotas is within the competence of the EU Council and is done through negotiations. Decisions on Baltic quotas are usually made at the October meeting of the EU Council of Ministers. Based on proposals from the

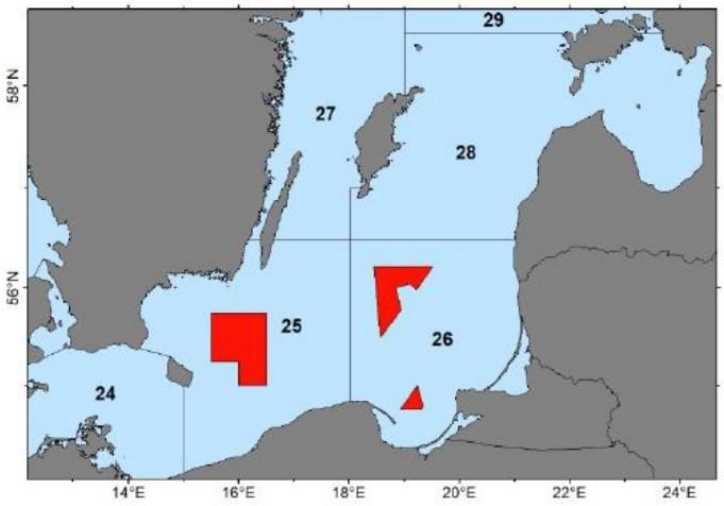
[1] The 12 m criterion was adopted to distinguish vessels that can be classified as small scale fisheries <12 m) in accordance with the provisions of Council Regulation 1198/2006.
[2] The total (annual, monthly) catch volume is the sum of the daily catch volumes reported by fishermen in their logbooks.
[3] The value of the catch was estimated based on the average annual price of fish of each species in a given year and the volume of catch.
[4] Annual or monthly fishing effort was defined as the sum of days in which a fishing vessel reported catching any amount of fish (the maximum theoretical number of days for one vessel is 365, for two vessels 730, for 10 vessels 3650, etc.)
[5] Fishing effort in terms of the number of fishing vessels was determined by the sum (annual or monthly) of all units that reported at least one fishing day (in a year or month). In statements containing fishing vessels by gear used, the number of vessels may be duplicated if a vessel fished with more than one gear (gear group) in a given year or month.
[6] Code of Responsible Fisheries https://www.fao.org/3/v9878pl/v9878pl.pdf, access date: 28.03.2022 r.
[7] Treaty on the Functioning of the European Union (OJ EU of 26.10.2012 C 326/47)

European Commission, the Council's agreed position is reflected in the annual regulation on the distribution of fishing quotas, i.e. quotas to be shared among eligible EU member states, including Poland. The Regulation on the Distribution of Fishing Quotas for 2018[8] introduced an eight-week closure period, from July 1 to August 31, to provide protection for Atlantic cod spawning stocks in subdivisions 25-26 of the eastern Baltic Sea.

Management of economically important fish stocks is based on multi-year management plans[9]. Established in accordance with Regulation (EU) 2016/1139 of the European Parliament and of the Council of July 6, 2016, the multi-year plan for cod, herring and sprat stocks in the Baltic Sea[10], the so-called multispecies plan, introduced areas of fishing prohibition in cod spawning areas, effective from May 1 to October 31. According to scientists, no-take areas are a sufficient protective measure for the eastern cod stock.

According to the current legislation, closed areas are located in basins: Bornholm, Gdansk and Gotland.

Figure 1. Areas of zones closed to fishing from May 1 to October 31 (source: ICES)



The Baltic Sea Plan is the first established plan under the new EU fisheries policy. Cod, herring and sprat are species that are heavily fished in the Baltic Sea. In practice, the size of cod stocks affects the size of herring and sprat stocks, and vice versa. According to the adopted Plan, management is to be based on the most up-to-date scientific, technical and economic data. The provisions in the Baltic Sea Plan are also intended to ensure that key tenets of the Common Fisheries Policy are carried out, such as the commitment to land[11] (so that fishermen do not discard fish they have already caught that they consider inferior, for example) and regional governance (a greater role for interested member states in the lawmaking process).

Pursuant to the Prime Minister's Order of October 27, 2021 on the detailed scope of activities of the Minister of Agriculture and Rural Development (Journal of Laws 2021, item 1950), the Minister of

[10] Regulation (EU) 2016/1139 of the European Parliament and of the Council of 6 July 2016 establishing a multiannual plan for cod, herring and sprat stocks in the Baltic Sea and the fisheries exploiting those stocks, amending Council Regulation (EC) No. 2187/2005 and repealing Council Regulation (EC) No. 1098/2007 (OJ EU 15.7.2016 L 191/1)

[11] article 15 of Regulation (EU) No. 1380/2013 of the European Parliament and of the Council of 11 December 2013 on the Common Fisheries Policy, amending Council Regulations (EC) No. 1954/2003 and (EC) No. 1224/2009 and repealing Council Regulations (EC) No. 2371/2002 and (EC) No. 639/2004 and Council Decision 2004/585/EC (OJ 28.12.2013 L 354/22)

Agriculture and Rural Development is the public administration body in charge of the government administration department of fisheries.

The principal legal act in Poland, establishing rules for the practice of fishing, is the Act of December 19, 2014 *on Maritime Fisheries* (Journal of Laws 2022, item 540), which came into force on March 4, 2015, and repealed the Act of February 19, 2004 on Fisheries (Journal of Laws 2004 No. 62, item 574, as amended). The current law specifies the rules on the performance of fishing, the scope of tasks and the competence of the authorities with regard to the granting, revocation and suspension of fishing privileges, as well as the rules on the supervision of marine fisheries and the landing and handling of marine organisms. Detailed regulations are contained in the implementing acts of the Marine Fisheries Law. The performance of commercial marine fishing is a regulated activity. In order to operate it, one must be a shipowner, and the vessel must be listed in the register of fishing vessels (Article 13 of the Marine Fisheries Law), maintained by the minister in charge of fisheries. Once these conditions are met, a fishing license is issued (Article 33 of the Marine Fisheries Law), which confirms the right to engage in commercial fishing. In addition, the performance of commercial fishing in a calendar year requires a special fishing permit (SZP) (Article 40 of the Marine Fisheries Law). The SZP is issued upon application by the owner of a fishing vessel, which is submitted by October 31 of the year preceding the year for which the special fishing permit is to be issued. Scientific research fishing and recreational fishing also require appropriate permits (Article 84 and Article 90 of the Marine Fisheries Law, respectively). A package of detailed regulations governing the performance of fisheries has been issued for the Marine Fisheries Law. Among the most relevant from the point of view of fishing are the Regulation on the Distribution of Fishing Quotas[12] and the Regulation on Detailed Conditions for Commercial Fishing[13].

If a permanent navigational obstacle (in the case of OWF BIII, this may be the entire area specified in the PSZW permit) is identified by the relevant Marine Offices' cells, it is marked on maps accordingly, and in the case of an impossible obstacle threatening navigation, a safety zone closed to navigation, anchoring, water sports and fishing is established around it. It forms a circular area with a radius of 500 m from the location where the navigation obstacle was revealed. Under Article 24 of the Act on Maritime Areas of the Republic of Poland and Maritime Administration[14], the decision to establish a zone is made by the director of the relevant maritime office at the request of subordinate units of the office responsible for the safety of navigation. The decision is issued in the form of an order published in the Official Gazette of the relevant province. A navigation exclusion zone is used for safety reasons for developments in maritime areas. An application for the establishment of an exclusion zone and the justification for its introduction is submitted to the director of the relevant maritime office by the investor. The abolition of the safety zone is carried out by order of the director of the competent maritime office.

3. Characteristics of fisheries in the OWF area BIII

3.1. Species of fish subject to fishing found in the area of the farm

In the area of the BIII offshore wind farm and buffer zone, 15 fish species were recorded in research catches carried out with pelagic trawl and bottom set surveys, of which 9 were the subject of commercial fishing (Table 1).

[12] Ordinance of the Minister of Agriculture and Rural Development of February 15, 2019 on the detailed distribution of general fishing quotas and additional fishing quotas (Journal of Laws 2019, item 370, as amended)

[13] Ordinance of the Minister of Maritime Economy and Inland Navigation of August 21, 2019 on the dimensions and protection periods of marine organisms and detailed conditions for commercial fishing (consolidated text Dz. U. 2021 item 2056 as amended)

[14] Consolidated text OJ 2022, item 457

Similar to the total Baltic catches of the Polish fishing fleet, the most important fish species caught in the area of squares M7, M8, N7, N8 were cod, herring, sprat and flounder.

The volume of catches of Baltic cod of the Polish fishing fleet in 2015-2020 fluctuated between 0.47-13.6 thousand tons, herring 37.4-50.9 thousand tons, Baltic sprat 60.1- 74.5 thousand tons and flounder 9.4-16.7 thousand tons.

Table 1. Summary of species found in research fisheries in the area of the BS III OWF and in commercial fisheries in the area of squares M7, M8, N7, N8 and Polish Baltic fisheries in total in 2015-2020.

Species	Average annual catch 2015-2020 (kg)	
	M7, M8, N7, N8	Total Baltic
Stickleback	-	-
Stickleback	-	-
Dobijak	2800	17394000
Cod	865753	42961588
Plaice	18523	2476481
Hound of the devil	-	-
Vixen	-	-
Salmon	522 kg / 1534 pcs.	209767
Skarp	17877	333039
Orchid	484414	82124562
Sprat	327402	403419989
Herring	292693	251100157
Tasha	-	-
Eelam	-	4642
Zimnica	-	-

3.2. The abundance of species targeted by the fishery fisheries on an annual basis

In the survey catch, sprats (77.9%) were the most abundant species found in the BIII OWF and buffer zone, followed by cod (9.5%), herring (7.6%) and flounder (4.4%). Sprats and herring dominated the pelagic trawl fishery, while cod and flounder dominated the pound net fishery. In terms of weight, cod clearly dominated the survey catch (56.2% of the total weight of fish caught), followed by flounder (18.7%), sprat (17.6%) and herring (5.5%).

Commercial fishing, in the area of the four Baltic quadrants M7, M8, N7, N8 (i.e., wider than the research fishing region), was dominated by cod (54%), flounder (21%), sprat (16%) and herring (8%) in 2011-2013.

In comparison, in 2015-2020, commercial fishing, in the area of Baltic squares M7, M8, N7, N8, was dominated by cod (42% of the total weight of fish caught), flounder (23%), sprat (16.0%) and herring (14%).

3.3. Spatial distribution of species targeted by fisheries fisheries

As shown by ichthyofauna monitoring surveys, the distribution of the two most important fish species for fisheries (cod and flounder) in the area planned to be occupied by the farm varies during the year, which is primarily related to annual changes in water temperature, and to a lesser extent to the availability of the food base and migrations (foraging and spawning). During the winter period, cod are observed migrating from the farm area to deeper waters with higher temperatures. In summer, on the other hand, there was no relationship between water depth and the distribution of these fish. On the other hand, in the case of flounder, significant variation was observed in the abundance of these fish during different periods of the year. The highest concentrations were found in winter (January), which is associated with the migration of these fish from shallower waters (feeding grounds) to deeper waters (spawning grounds). At the same time, significant spatial variation in the occurrence of flounder was observed - more numerous in the zone proper compared to the buffer zone. A similar pattern was also observed in late spring and summer. It should be noted that the area of the OWF (see Appendix H of the Report), during the winter period - which is the highest fishing season for these fish - is not a target spawning ground for flounder (due to low salinity), nor is it a habitat for them.

It should be noted that the area of the farm is a small fraction of the area of possible activity of a fishing vessel during a fishing trip. Therefore, the degree of spatial differentiation of species within the Project only to a small extent, and only in the case of demersal species, can be relevant to assessing the fishing attractiveness of the entire area of operation of the fishing units concerned. In addition, bearing in mind, the dynamics and scale of movements of individual pelagic species (sprat and herring), it is pointless to analyze which part of the area of OWF BIII may be more attractive for fishing. The assessment should therefore focus on the impact of the farm's location itself on the region's fishing opportunities.

3.4. Fishing activities in the study area research

3.4.1. The volume of fish catch in the area of OWF BIII

The total volume of fish catches in the area of the analyzed squares fluctuated from about 185 to 477 tons in 2015-2020. The volume of total catches of the Polish Baltic fleet during the same period ranged from nearly 129,000 tons to 152,000 tons. The analyzed square is a relatively small area compared to the rest of the area of potential interest for the fishing fleet. Also, the sheer size of the catches realized in these squares is small in relation to the Polish total Baltic catches (much less than 1%) or the average catches per unit area (more on this later in section 3.4.2). Therefore, it can be presumed that the observed annual changes in catches, may depend on the activity of a small and quite variable group of vessels and is dependent on the subjective choice of the fishing ground by the skipper of the fishing unit. The activity of these vessels, over the long term, is not necessarily linked to the same fishing squares.

Table 2. Comparison of catches in fishing squares M7, M8, N7, N8 with total Polish Baltic catches, 2015-2020

Year	M7, M8, N7, N8 squares	Total Baltic fishing	Squares M7, M8, N7, N8 /Total
	Tone	Tone	-
2015	337	134712	0.003
2016	477.6	133295	0.004
2017	403.8	133595	0.003

Year	M7, M8, N7, N8 squares	Total Baltic fishing	Squares M7, M8, N7, N8 /Total
	Tone	Tone	-
2018	265.9	151591	0.002
2019	372.3	141063	0.003
2020	184.8	128674	0.001

Table 3. The volume of catches in the area of Baltic squares M7, M8, N7, N8 and the estimated volume of catches in the area of the investment itself (2015-2020)

Year	Fishing in squares M7, M8, N7, N8	Estimated catches in IMF BIII
	Tone	Tone
2015	337	24.94
2016	477.6	35.34
2017	403.8	29.88
2018	265.9	19.68
2019	372.3	27.55
2020	184.8	13.67
Average	340.2	25.18

The main fish species caught in the area of the analyzed fishing squares were cod, flounder, herring and sprat. The average share of cod, which was the most important species caught, in the volume of catches in 2015-2020 was 42%, flounder 23%, herring 14% and sprat 16%.

Table 4. Catch volume in fishing squares M7, M8, N7, N8 in 2015-2020, by major species

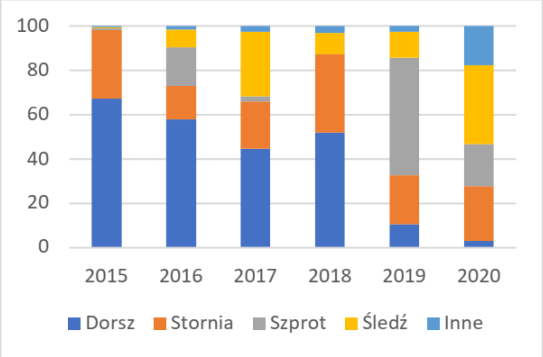
Species	2015	2016	2017	2018	2019	2020
	t	t	t	T	t	t
Cod	226.7	276.5	179.8	137.8	39.2	5.8
Orchid	103.9	71.8	86.9	93.9	82.2	45.7
Sprat	2.8	83.2	8.5	0.4	197.8	34.8
Herring	1.8	39.0	117.7	25.1	43.4	65.7
Other	1.8	7.1	10.9	8.7	9.8	32.8
Total	337	477.6	403.8	265.9	372.3	184.8

Over the analyzed years, the species structure of fish caught in the area of squares M7, M8, N7, N8 has been changing, although it is difficult to catch a clear and lasting trend in the noted changes. In general, a systematic and significant decline in the volume of catches and their value for cod is noticeable. With the exception of 2016 and 2019, the share of sprat was insignificant.

Information provided by scientists confirms that the eastern stock cod is in critical condition. Population status is affected by hydrological conditions. Record high water temperatures have been recorded in the Baltic, resulting in an increase in oxygen-deficient areas, lower salinity, and further deterioration of conditions for successful cod spawning. The growth of the gray seal population in the Baltic, over the

past two decades, has contributed to a sudden increase in cod feeding. Subsequently, the European Commission approved emergency measures banning commercial cod fishing in parts of the Baltic Sea by Executive Order 2019/1248 of July 22, 2019, with immediate effect.[15] The ban has been consistently extended, and is currently in effect under Council Regulation (EU) 2021/1888 of October 27, 2021.[16] The ban covers all fishing vessels and applies in those areas of the Baltic Sea where the largest portion of the stock is found, except for certain specified derogations.

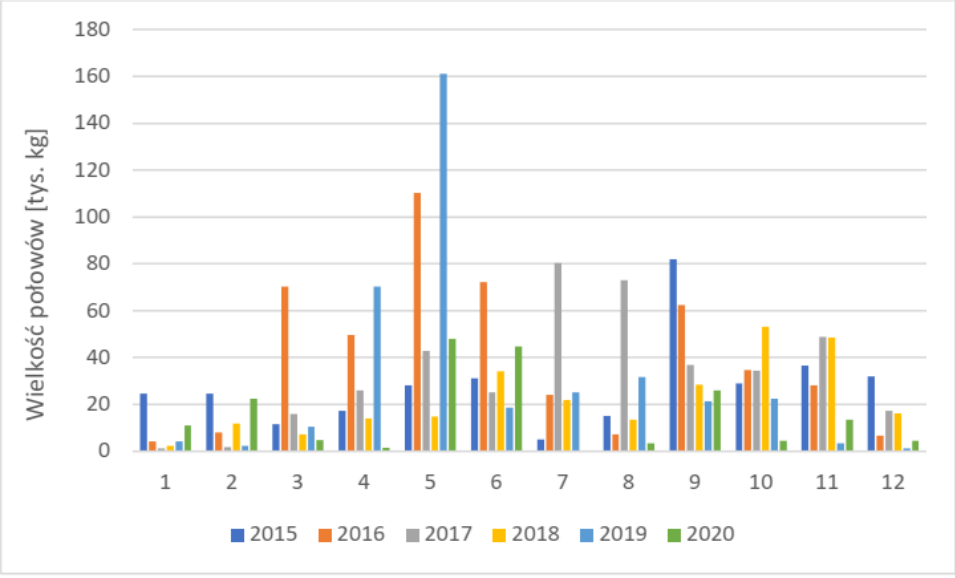
Figure 2. Species structure of catch volumes in the area of squares M7, M8, N7, N8 in 2015-2020



Dorsz	Cod
Stornia	Orchid
Szprot	Sprat
Śledź	Herring
Inne	Other

The analysis of monthly changes in catch volumes conducted for 2015-2020, despite notable significant differences for some months, showed that, in general, the period of lowest fishing fleet activity for the years analyzed was the winter months (December-February). The highest catch volumes occurred in May. A comparison of monthly catch volumes in quadrants M7, M8, N7, N8 is shown in Figure 3.

Figure 3. Seasonality of fish catch in the area of squares M7, M8, N7, N8 in 2015-2020



[15] Commission Implementing Regulation (EU) 2019/1248 of July 22, 2019, laying down measures to alleviate a serious threat to the conservation of the Eastern Baltic stock of Atlantic cod (Gadus morhua)

[16] Council Regulation (EU) 2021/1888 of October 27, 2021 fixing the fishing opportunities for 2022 for certain fish stocks and groups of fish stocks in the Baltic Sea and amending Regulation (EU) 2021/92 as regards fishing opportunities in other waters

Wielkość połowów [tys. kg]	Catch volume [thousand kg]

3.4.2. Fishery productivity in the BIII OWF area

In relation to the average size of Polish Baltic catches, converted to area (fishery productivity), realized in squares lying (partially or fully) in the Polish economic zone, the fishery productivity observed in the analyzed squares can be assessed as low. Between 2015 and 2020, it accounted for about 3.1% to about 7.9% (from about 116 $^{kg/km2}$ in 2020 to about 302 $^{kg/km2}$ in 2016) of the productivity observed in the POM. The average fishery productivity in fishing squares M7, M8, N7, N8 for 2015-2020 was about 215 $^{kg/km2}$ (which accounted for about 5.4% of POM productivity).

3.4.3. The amount of fishing effort in the area of OWF BIII

In 2015-2020, in the area of fishing quadrants M7, M8, N7, N8, there were 37 (2020) to 66 (2015) fishing units out of 803 (2020) and 816 (2015) total Baltic vessels registered in the Polish register. During the period under review, a steady decline in the number of units involved could be observed.

Table 5. Number of vessels involved in fishing in squares M7, M8, N7, N8 (2015-2020)

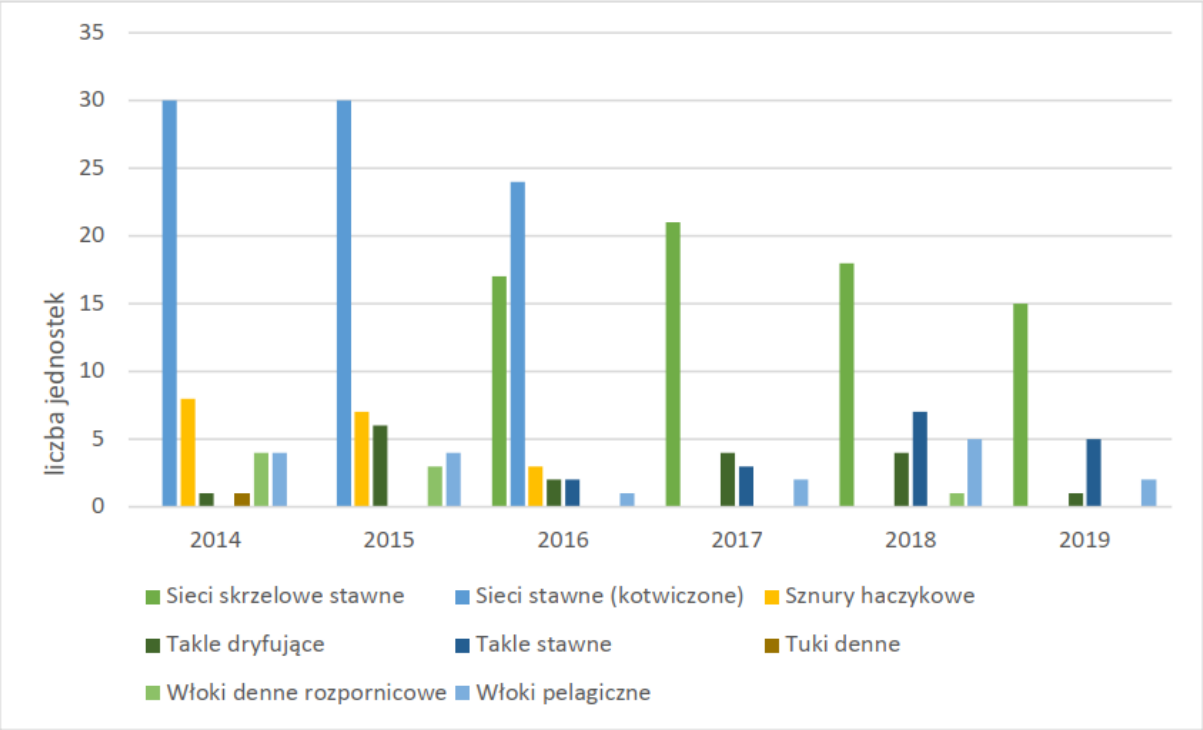
Year	2015	2016	2017	2018	2019	2020
Number of ships	66	56	56	52	40	37

The main gear used for fishing in the study area in 2015-2020 was set nets, as shown in Table 6 and Figure 4 .

Table 6. Number of vessels engaged in fishing in squares M7, M8, N7, N8 (2015-2020) by gear

Fishing gear	2015	2016	2017	2018	2019	2020
Jointed gillnets	0	20	28	26	21	21
Fixed (anchored) nets	33	27	0	0	0	5
Longlines	7	1	0	0	0	0
Drifting longlines	7	9	22	11	8	9
Joint tacos	0	0	3	13	8	0
Bottom tucks	0	2	0	0	0	0
Strut bottom trawls	34	19	15	18	11	10
Pelagic trawls	3	3	7	3	4	9

Figure 4. Number of vessels engaged in fishing in squares M7, M8, N7, N8 (2015-2020) by gear



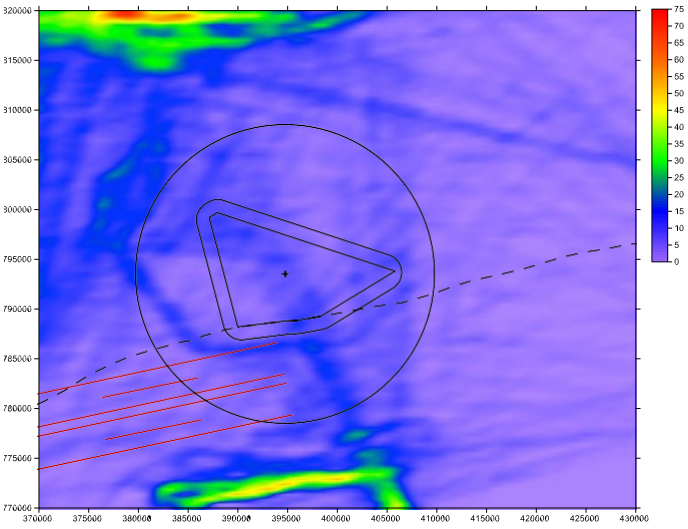
Liczba jednostek	Number of units
Sieci skrzelowe stawne	Jointed gillnets
Sieci stawne (kotwiczone)	Fixed (anchored) nets
Sznury haczykowe	Longlines
Takle dryfujące	Drifting longlines
Takle stawne	Joint tacos
Tuki denne	Bottom tucks
Włoki denne rozpornicowe	Strut bottom trawls
Włoki pelagiczne	Pelagic trawls

The average annual fishing effort (sum of fishing days of all fishing vessels fishing in squares M7, M8, N7, N8) in the analyzed area was 421 days. This represented just over 0.6% of the average effort of the Polish Baltic fleet overall (about 68,000 days per year) in 2015- 2020. Like the number of ships, it varied from year to year, with a marked decline over the years analyzed, particularly sharp in 2019 and 2020.

3.4.4. Fishing vessel traffic in the study area based on AIS data

The figure below shows visualizations of the data collected by a measurement set containing an AIS (Automatic Ship Identification System) sensor. According to the Ordinance of the Minister of Transport, Construction and Maritime Economy of November 29, 2011 on the categories of vessels exempted from the requirement to equip with Automatic Identification System (AIS) equipment (Journal of Laws 2014, item 651), fishing vessels with an overall length of less than 15 meters are exempted from the obligation to equip with AIS equipment. A detailed description of vessel traffic is included in Section 14 of Volume III of the ROIA.

Figure 5. Number of fishing vessel crossings in the study area recorded during the annual vessel traffic monitoring conducted in 2013-2014



Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

The area of OWF BIII is used to a relatively small extent by fishing vessels moving between the ports of Leba and (to a lesser extent) and Ustka to the fishing area within the Słupsk Trough. The intensity of fishing in the Slupsk Trough area can be seen in the upper left corner of the square. There are also traces of trawling or netting in the area of the planned project, especially its NW corner, but their number is not great. The number of registered vessels (in 2013-2014) in the observed area in the period was 123 units. More detailed data characterizing these vessels (e.g., port of registration) is not available.

Fishery data (FMC) shows that 52 units of fishing vessels were fishing in the area of the four analyzed fishing squares in 2018. As shown in the VMS data recorded (figure below) by fishing vessels over 12 meters in length from Leba going to fish in the waters of the Slupsk Trough, they most often sail a course that crosses the edge of the eastern area of the farm or sail past its border.

The above information is also confirmed by the latest Helcom data, according to which the intensity of fishing vessel traffic in the project area is low, as shown in Figure 7 below.

Figure 6. Routes of fishing vessel traffic in the area of the planned project based on 2016 Helcom data.

1. Introduction

This section presents the characteristics of ship traffic in the area of the planned BIII OWF and in its zone of potential impacts. This characterization was developed primarily on the basis of the results of annual vessel traffic monitoring surveys conducted in 2013-2014 (see Appendix N of the Report).

For the purpose of describing the current state, materials from the work on the development of the Draft Spatial Plan for Polish Marine Areas and numerous HELCOM studies and data were also used, as well as the results of surveys conducted in areas adjacent to the BIII OWF area.

2. Legal conditions for shipping maritime

All seagoing vessels, regardless of flag, are subject to a series of regulations describing the standards that vessels must meet before they are allowed to operate at sea. This applies to all types of vessels in coastal shipping, domestic shipping, or international traffic. The regulations cited below cover all aspects of ship operation - from technical, to environmental protection, to crew time regulations (which has a huge impact on shipping safety). The main legal regulations governing traffic in attrition areas, i.e. where the usual routes on which ships navigate converge or intersect and where the volume of traffic needs to be strictly regulated, are the provisions of the International Maritime Organization in London (IMO), which acts as the formal regulator of ship traffic in areas under the jurisdiction of its member states and in international waters, which in practice means covering almost all maritime areas on Earth. In agreement with the IMO, local maritime administration offices (in Poland, the Maritime Offices in Gdynia, Slupsk and Szczecin) establish Traffic Separation Scheme (TSS), zones under special technical supervision (Vessel Traffic Control Systems - Vessel Traffic Service - VTS), in which there is an obligation for ships to report any maneuvering, the situation of entering and leaving the zone, crossing successive reporting points. In these areas, there is a system of close supervision of ship traffic (similar to that used in aviation), in which the ground center continuously supervises the safety of ship traffic, interferes with decisions made on the ship by ordering a change in speed, direction or rerouting.

In areas of the open sea, outside TSS and VTS zones, ship masters are not subject to the decisions of traffic surveillance centers and are free to decide the course and route on which they will sail to their destination port, unless a rescue operation at sea is currently underway in their area of residence and they are brought into this operation by the Rescue Coordination Center or other activities are being carried out, such as military exercises or construction work at sea, etc. In such a situation, they should immediately submit to the decisions issued by the supervision of these projects announced by the NAVTEX Nautical Information Broadcasting System. In other situations, they are guided by good maritime practice and the indications of the local locals. Notwithstanding the above, customary routes are used in shipping, taking into account safe distances and navigational obstacles, as well as the application of international regulations on the prevention of collisions at sea.

In Poland, Polish seagoing vessels are obliged to follow the recommendations of the Baltic Location (for the area of the Polish Economic Zone, territorial and internal waters, the Baltic Location 502 was issued. The Hydrographic Office of the Navy is responsible for the timeliness of the information contained in the locia. On ships of other flags, English-language (or issued in the language of the ship) equivalents of the Polish Baltic Locations are most often used. The English-language edition of Sailing Directions for the South Baltic area is called Baltic Pilot NP19 Vol II. Both documents include information on customary and mandated routes, TSS routes, traffic surveillance systems, information on hydrometeorological conditions in the described body of water, legal regulations and local rules for ports and approaches to those ports, information on the rescue system, radio communications, etc. neither loco prescribes sticking to established routes outside the TSS and VTS systems. Usually, customary sailing routes (usually

by the shortest route connecting the port of departure with the port of destination) are treated as recommended routes, unless the level of safety is understated on them, in which case the captain decides to go based on his experience and at his own risk, in which case such a customary route is not treated as a recommended route. Most often, locjes provide only general information on the route of passage, setting important limitations due to geographical conditions, regulations of the countries to which the locjes apply.

The passage routes of commercial, special, passenger, fishing and other vessels observed in the BIII offshore wind farm area - with the exception of the Traffic Separation Route (TSS Slupsk Shoal) located south of the farm's location - are not established as mandatory and their alignment depends mainly on the current shipping situation, obstacles located in the area (e.g., hydrotechnical structures such as offshore wind farms), current hydrometeorological conditions, etc. Thus, there is no need to regulate the routing of these routes in an official manner. When an obstacle arises (e.g., construction of an offshore wind farm), captains will make other sailing routing decisions that are optimal from their point of view, and traffic will naturally shift to areas that are convenient for navigation. This does not change the fact that at the moment registered a significant number of passes through the area of the planned farm belong to fishing, recreational and special vessels. Fishing vessels moving into the fishing areas benefit from the fact that the area currently allows free navigation. Recreational ships pass through the area on their way to Sweden, special ships (Navy ships, Coast Guard, Fisheries Surveillance) stay in the area following their own plans and needs, of which we have no information, and other ships avoid it, as it does not lie on any of the routes used for navigation.

The spatial development plan for the Polish maritime areas (PZP POM)

In 2021, a POM was developed and passed at a scale of 1:200,000. It was adopted by Cabinet decree on April 14, 2021. (Journal of Laws 2021, item 935), which became effective on May 22, 2021. Its provisions specify prohibitions or restrictions on the use of the area, permissible public purpose investments and conditions for the use of water bodies.

In the POM, 19 basins with the primary function of transportation were separated, with a total area of more than 6.7 square $^{\text{kilometers}}$, accounting for 20.65% of the area of the POM. More than 2,300 square kilometers, or about 7% of the POM area, have been allocated for renewable energy in the POM. Navigation safety is to be ensured by maintaining an adequate distance between areas with a primary function of transportation and areas with a primary function of renewable energy generation. Artificial islands, offshore wind farm structures and equipment, including offshore wind farms as well as the internal connection infrastructure of offshore wind farms, may not be closer than 2 nautical miles from the boundary of water bodies with the primary function of transportation, according to the Draft Plan and the issued PSZW Decision (No. MFW/2/12).

The ordinance stipulates that the erection of offshore wind turbines is permitted only in basins with the primary function E - renewable energy generation. The BIII offshore wind farm area is located within the boundaries of the POM.45E basin. The draft POM assumes an additional 9 permissible functions for the POM.45E basin:

1) aquaculture (A);
2) research (N);
3) cultural heritage (D);
4) technical infrastructure (I);
5) exploration and prospecting of mineral deposits and extraction of minerals from deposits (K);

6) fishing (R);

7) artificial islands and structures (W);

8) transportation (T);

9) tourism, sports and recreation (S).

Decisions regarding restrictions on navigation through the creation of a restricted vessel traffic zone can be made by the Maritime Administration.

According to the POM.45E basin charter, the following conditions are indicated in the context of OWF construction:

- At the time of commencement of the project of erecting artificial islands and structures, it is required to impose, by a decision of the competent director of the maritime office, a prohibition of navigation in the body of water occupied for construction in terms of safety, along with a 500 m safety zone around the body of water for the duration of construction;
- During the operation of offshore wind power plants, it is required to introduce, by decision of the competent director of the maritime office, restrictions on the operation of navigation in the safety zones established for each turbine and in places that threaten the safety of the internal technical infrastructure.

In addition, in the 45.E basin, it is recommended that a 100-meter safety zone be established around any functioning offshore wind turbine structure and that the development be laid out in such a way as to allow a transport corridor for vessels up to 150 meters in length.

3. Characteristics of ship traffic in the area of OWF BIII

As a result of the monitoring of ship traffic in 2013-2014 in the area of OWF BIII, information was collected on the basis of AIS (Automatic Identification System for Ships) data on the positions, movement and berthing of various types and purposes, which temporarily stayed in the area limited by a radius of 15 km from the focal point of the farm.

The survey covered areas of the BIII OWF field, the one-mile buffer zone and the adjacent area. A measurement set, including an AIS (Automatic Ship Identification System) sensor with a recorder, has been installed in the OWF area to measure and record AIS signals from vessels visible to the receiver, for navigational analysis.

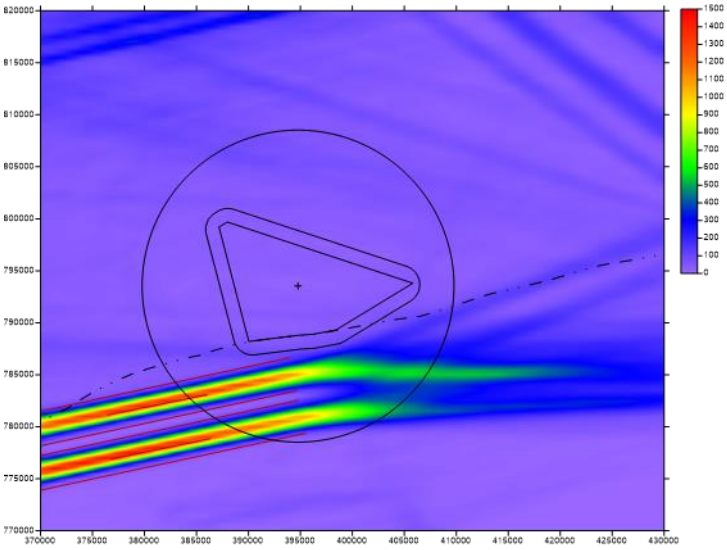
3.1. Intensity of traffic of ships

As a result of the measurements, information was collected on the positions, movement and berthing of 2653 vessels of various types and destinations that temporarily stayed in the area bounded by a radius of 15 km from the focal point.

The data was collected in one aggregate and in 6 groups specific to the construction and purpose of ships sailing in the region. These included commercial vessels, fishing vessels, passenger vessels, tankers, recreational vessels and all others that did not meet the main characteristics for the first five groups, which were referred to as special vessels.

Figures 1- 1 show the information that was obtained by studying the number of ship passes through areas of 500 x 500 meters.

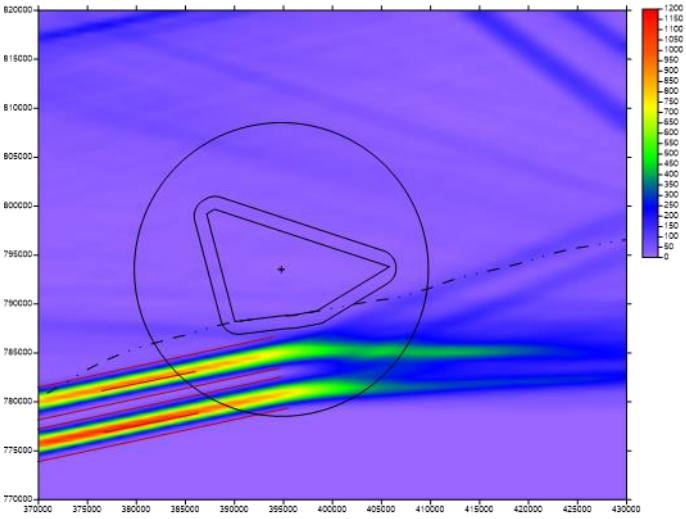
Figure 1. Intensity - the number of passages of a single ship through a square of 500 meters observed during one year. The study did not take into account the presence of IM survey vessels in Gdansk, i.e. IMOR, Baltic-i and Saphira -conducting measurements in the area of the BSIII offshore wind farm



Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

Visible in the figure (in the upper left corner of the region, the densities of passages from east to west correspond to the usual shipping routes of ships from Klaipeda, Riga to the region of the ports of Szczecin, Swinoujscie and Sasnitz and Mukram.

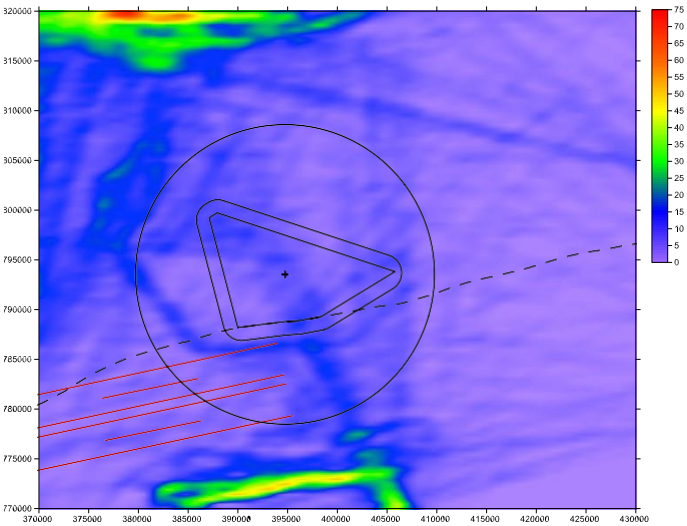
Figure 2. Observed numbers of commercial ship crossings in the study area



Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

Nearly all merchant ships moved on straight courses along recognized and recommended shipping routes, which is evident in the density of the routes of these vessels. This is particularly evident in the area south of the OWF BIII field, where the Traffic Separation System - Slupsk Shoal runs, leading commercial vessels from the Gdansk Bay area towards the Szczecin- Swinoujscie port complex and towards the Danish Straits.

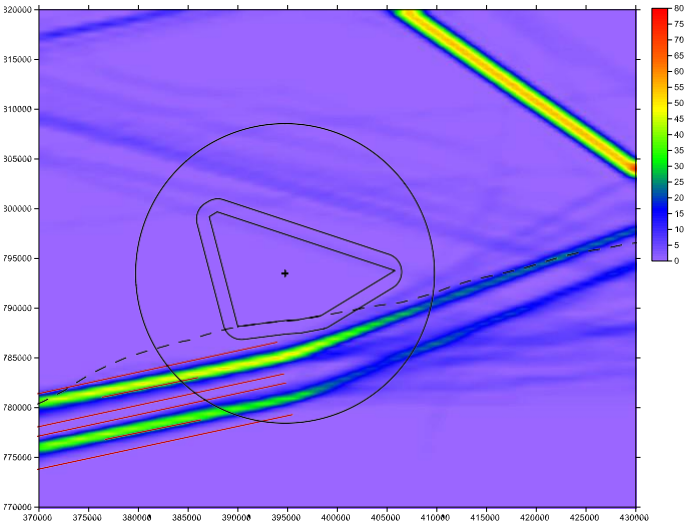
Figure 3. Observed numbers of fishing vessel crossings in the study area



Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

In the southern part of the BIII OWF area, the intersection of routes of fishing vessels heading from the ports of Leba and Ustka to the fishing area within the Slupsk Trough is visible. The intensity of fishing in the Slupsk Trough area can be seen in the upper left corner of the square. Traces of trawling or netting can be seen throughout the area of the planned project, but their number is not great. This is evidenced by the complicated passage routes of fishing vessels.

Figure 4. Observed numbers of passenger ship crossings in the study area

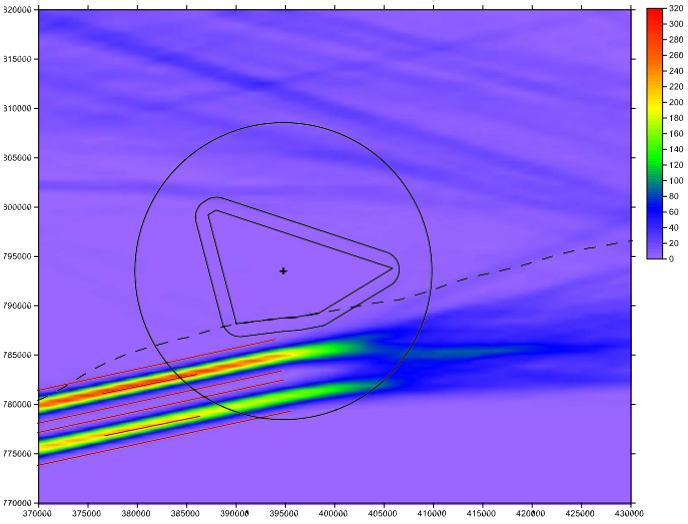


Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

Large passenger ships use established shipping routes, mainly the Slupsk Shoal Traffic Separation Zone, located south of the study area. Passenger-cargo ferries, running on fixed lines, use the usual Gdynia (Gdansk) - Karlskrona route, on which they run regularly throughout the year. The apparent three passage routes of passenger ships north of the upper boundary of the OWF area should be considered as not subject to any offshore traffic rules. The activities of the captains of these ships are aimed at shortening their passage route from Polish ports to Swedish ports or towards the isthmus between Bornholm and Sweden, called the Bornholm Strait. They are not a typical routine activity. The law allows

captains to choose this route. With the change in the navigational situation (the development of this area of OWF BIII), this traffic will naturally move out of the area.

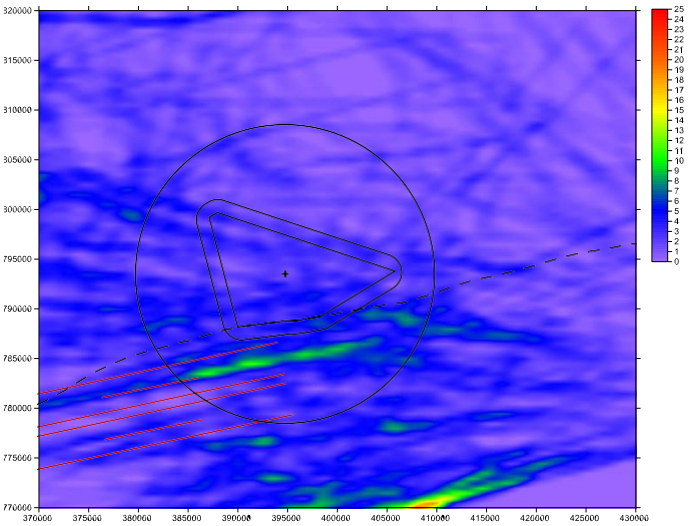
Figure 5. Observed numbers of tanker passages in the study area



Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

Tankers like merchant ships mainly traveled along prescribed routes (the route south of the field and east and north of the OWF, where the usual shipping route for tankers and large bulk ships passes through, planned as the future deepwater route D, designated for the largest merchant ships and for tankers). A number of small tankers choose routes that run north of the area of the planned OWF. These routes should be considered not subject to any offshore traffic rules. The activities of the captains of these ships are aimed at shortening their passage route from Polish ports to Swedish ports or towards the isthmus between Bornholm and Sweden, called the Bornholm Strait. The law allows captains to choose this route. With the change in the navigational situation (the development of this area of OWF BIII), this traffic will naturally move out of the area.

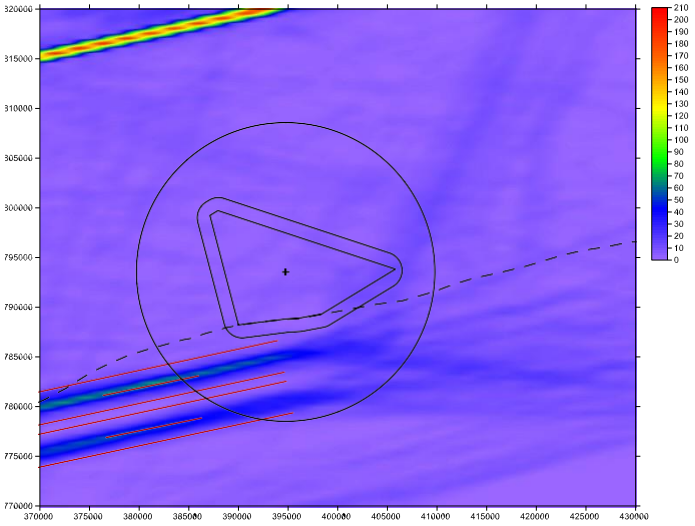
Figure 6. Observed numbers of recreational vessel passages in the study area



Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

Vessels designed for recreation, whether sailing or motor, most often take coastal routes, sailing from port to port. The figure clearly shows the density of routes in the area of the port of Leba, where there is a modern marina. A portion of the sailing vessels chose routes passing through IMF BIII, probably heading for Danish or Swedish ports. This activity lacks a clear pattern except for the choice of coastal routes leading from east to west and vice versa in close proximity to the shore, which helps to raise the value of amateur sailing.

Figure 7. Observed volumes of special vessel transitions



Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

Like merchant ships, larger research vessels, tugboats, border guards, SAR vessels and other commercial vessels than cargo ships moved on straight courses along recognized and recommended shipping routes, as evident by the density of the routes of these vessels. This is particularly evident in the area south of the OWF BIII field, where the recommended shipping route leading commercial ships from the Gdansk Bay area towards the Szczecin-Swinoujscie port complex and towards the Danish Straits runs.

The Baltic Sea is one of the most crowded seas in the world. It provides a route of connection between the Baltics and the rest of the world, allowing the constant movement of commercial vessels, ferries, passenger ships and pleasure craft.

However, due to the location of the planned project outside the area of intensive shipping traffic, it was found that there were no threats from the traffic of commercial vessels of all sizes, tankers and passenger ships. The project will pose some difficulties for fishing vessels heading from the ports of Leba and Ustka to the fishing grounds located north of the BIII OWF. Recently, the number of fishing vessels has decreased significantly due to the European Union's maritime policy and the reduction of the fishing fleet. The number of fishing vessels currently passing through the project area was estimated at 123 per year. The movement of yachts and non-commercial vessels will also not be a hindrance and will not affect the safety of the project, as these vessels will naturally divert to the recommended shipping lanes once the project is completed and the area is closed to navigation.

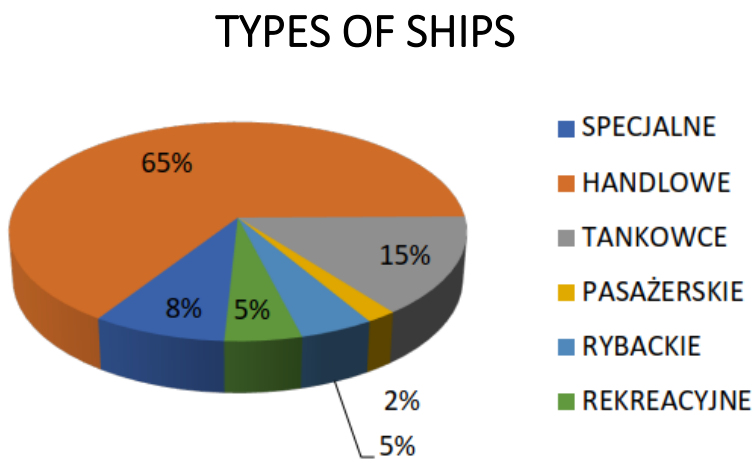
The area of the planned investment already during the construction of the wind farm, at the request of the investor, should be recognized by the Maritime Office in Slupsk as temporarily closed or as an area of restricted sailing due to the ongoing construction work. Upon completion of these works, the area, as an artificial island, may be declared a closed area for navigation and fishing, accessible only to ships and helicopters servicing the investment and services such as the Maritime Search and Rescue Service.

At the request of the investor, this decision is made by the Maritime Office competent for the area - in this case, the Maritime Office in Slupsk, based on the applicable regulations.

3.2. Qualitative composition of traffic of ships

The breakdown of the vessels registered by the AIS receiver device in terms of the detailed breakdown in the groups of vessels adopted for analysis is shown in the following figures Graphically these data are shown in Figure 8, and in terms of size parameters are shown in Figure 9.

Figure 8. Division of units by type of vessels registered by the buoy ZOO_BŚ3_001



SPECJALNE	SPECIAL
HANDLOWE	COMMERCIAL
TANKOWCE	TANKS
PASAŻERSKIE	PASSENGERS
RYBACKIE	FISHING
REKREACYJNE	RECREATIONAL

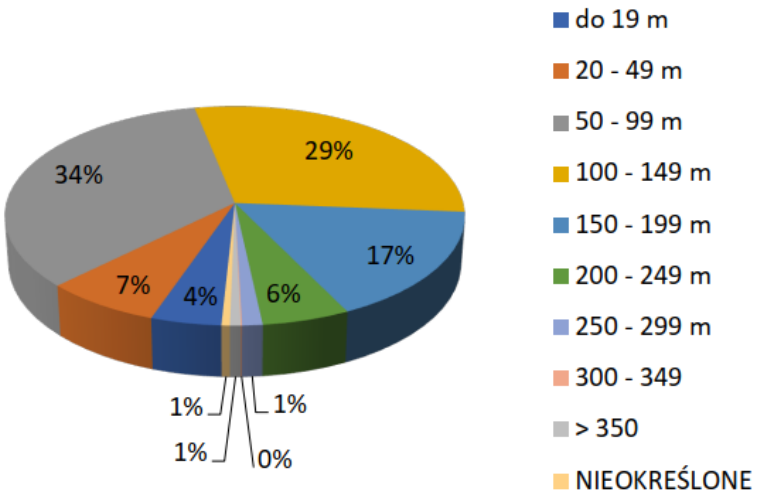
Figure 9. Breakdown of vessels by vessel size as recorded by the ZOO_BŚ3_001 buoy (length is given in meters)



do 19m	up to 19m

NIEOKREŚLONE	UNLIMITED

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

The largest quantitative share of shipping in the area is held by commercial vessels (1,740 units), the second group clearly larger than the others are tankers (389 units), the share of fishing vessels is at the level of 123 units and is periodic, which is related to the cycle of fishing seasons imposed by European Union law, recreational vessels at the level of 128 units (their share is significantly higher in the summer season), while passenger ships are in the area of OWF BIII incidentally, mainly during the tourist season, i.e. from May to September (50 units). All other units of other types and purposes are a total of 223 special units, which, considering the great diversity of these units and the fact that intensive studies of the bottom, water, birds, mammals were carried out during the period, it should be considered that these units in the area are not many (the units performing measurements and surveys for this project were removed).

The largest number of medium- and large-sized vessels (from 50 to 199 meters in length - a total of 2,128 vessels) sail in the area, which corresponds to the typical size of commercial vessels and tankers operating in the shallow waters of the Baltic Sea. There have only been 18 vessels longer than 300 meters, and they always head for deepwater route D passing northeast of the planned project area.

4. Traffic volume forecasts ships

The Baltic Sea is one of the world's most congested seas, with maritime transport accounting for 15% of the world's seaborne freight. The Baltic Sea provides a route of connection between the Baltic countries and the rest of the world, allowing the constant movement of commercial vessels, ferries, passenger ships and recreational vessels. Based on 2015 data, it was estimated that about 7,900 vessels registered with the International Maritime Organization in London (IMO) operated in the Baltic Sea, of which 48% were cargo vessels, 22% were tankers, 5.4% were passenger vessels, 5.2% were service vessels, 4.3% were container vessels, 4.1% were fishing vessels, 3.1% were RO-RO vessels, 7.4% were other vessels, and 0.5% no information was available (HELCOM 2018). Although these ships still enter and leave the basin, according to HELCOM, at any given time, there are about 1,500 IMO-registered vessels in the Baltic Sea.

Error! The source of the reference cannot be found. depicts vessel traffic in the southern and western Baltic Sea obtained from information from the AIS automatic identification system. The figure shows an example situation captured as of 06/03/2022, showing the number of ships and their main types.

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

The intensity of shipping traffic and the identification of shipping routes is shown in Figure 11, which shows the annual number of ships on these routes. Statistics show that there are about 2,000 ships in the Baltic Sea at any given time. An analysis of the structure of shipping types shows that cargo ship traffic dominates, a large group of ships are tankers of all types and passenger ferries and passenger ships. The intensity of the latter's traffic is highest between early May and late September.

To the north of the BIII offshore wind farm area runs a route (Route E) connecting the port of Klaipeda with the ports of the southern Baltic - mainly the ports of Swinoujscie, Sassnitz and Mukram. The main users of this route are freight-rail ferries (Mukram-Klaipeda) and cargo ships. Polish AIS stations (2015-2016 data) record that 761 ships pass through it. Mainly commercial vessels (46%), tankers (4%), ferries (45%) and others (5%) (IMG Consortium and MEWO et al. 2017).

To the north of the BIII OWF area runs a route connecting the ports of the Gulf of Gdansk with the Bornholm Strait (route D). In 2015-2016, 557 vessels used it (commercial 69%, tankers 24%, other 7%) (IMG Consortium and MEWO et al. 2017). AIS data indicate that in 2018-2019, vessels made about 600 trips along this route through the Baltic Power OWF area located about 2 km east of the Project area (MEWO and IMUMG Consortium, 2020). This route has been a component of the Polish Maritime Administration's planned deep-water route D of strategic importance (for large tankers and gas carriers) for many years. Due to the location decisions issued for the construction of offshore wind farms (PSZW), the Maritime Office in Gdynia, as part of its work on the draft POM, modified the route. Since the customary route in question has not previously passed through the Project area the above modification does not affect the conditions for implementation of the Project.

South of the BIII offshore wind farm area runs the second most heavily used customary shipping route (Route I), passing from east to west, south of Bornholm leading to Polish and Russian ports in the southern Baltic. Data recorded in 2015-2016 at Polish AIS stations indicated that the route was used by 5641 vessels. Mainly commercial vessels (78%), tankers (15%), passenger ships (1.5%), others (5.5%) (IMG Consortium and MEWO et al. 2017). AIS data indicate that in 2018-2019, ships made about 16,000 trips along this route (MEWO and IMUMG Consortium, 2020). The aforementioned TSS traffic separation system applies on this route

"Slupsk Shoal. IMO's Maritime Safety Committee, during its 102nd session, held November 4-11, 2020, adopted changes to the Traffic Separation System ("TSS" from Traffic Separation System) "Slupsk Shoal." The revised system became effective on June 1, 2021. Currently, the TTS "Slupsk Shoal" consists of three parts: western, central and eastern[1]. The northern branch of the route (Route F) carries ship traffic from

[1] official website of the Maritime Office in Szczecin: https://www.ums.gov.pl/bezpieczenstwo-morskie/przepisy-portowe-2/19-bezpieczenstwo-morskie/551-system-rozgraniczenia-ruchu-statkow-tss-lawica-slupska, access date: 10.05.2022 r.

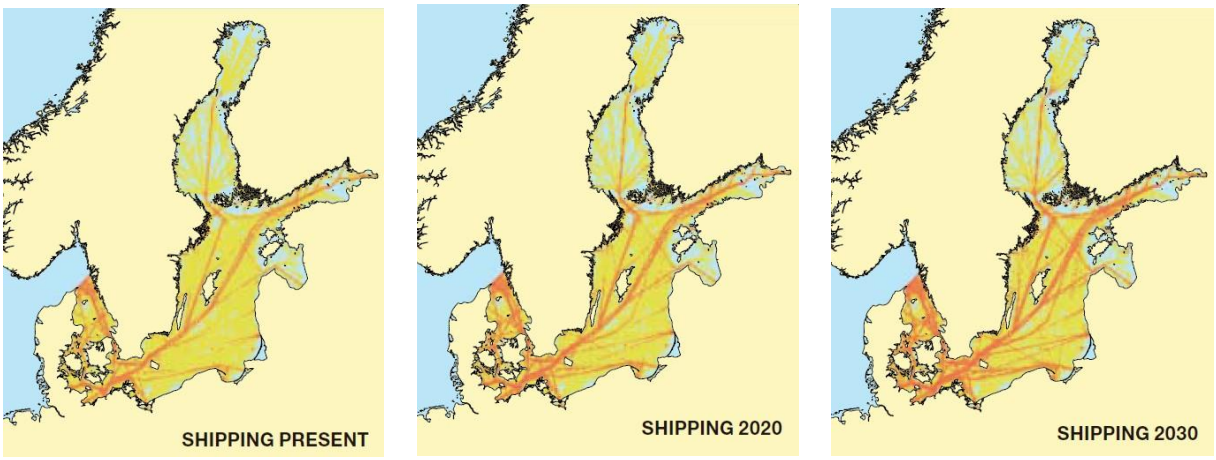
the area of the Danish Straits into the Gulf of Gdansk. After leaving the demarcation zone, the Slupsk Shoal heads for the ports of Lithuania and Latvia.

There are many more customary shipping routes than the routes indicated in Figure 11.

To the north of the BIII offshore wind farm area runs a route (Route E) connecting the port of Klaipeda with the ports of the southern Baltic - mainly the ports of Swinoujscie, Sassnitz and Mukram. The main users of this route are freight-rail ferries (Mukram-Klaipeda) and cargo ships. Polish AIS stations (2015-2016 data) record that 761 ships pass through it. Mainly commercial vessels (46%), tankers (4%), ferries (45%) and others (5%) (IMG Consortium and MEWO et al. 2017).

According to WWF projections, the number of ships is estimated to double by 2030, from about 3,000-5,000 ships per month to more than 9,000 ships each month. The size of ships sailing in the Baltic Sea will also increase. The WWF report predicts an increase in oil transportation - 64% by 2030. This huge growth in the shipping sector is mainly due to the expansion and construction of oil terminals on the shores of the Gulf of Finland and regional economic growth. In addition, the number of cruise ships in the area is increasing every year with a growing trend toward larger ships and international cruise ships.

Figure 12. Expected increase in traffic intensity of tankers, cargo ships and passenger ships



Source: https://wwfeu.awsassets.panda.org/downloads/wwf_future_trends_in_the_baltic_sea_2010_1.pdf (access date: 06.03.2022 r.)

5. Data on accidents marine

HELCOM data show that between 2011 and 2015, 1520 accidents occurred in the Baltic Sea, about 300 incidents per year. (HELCOM 2018). The most common causes of emergency incidents between 2011 and 2015 were shoaling (21%), equipment damage (21%) and collisions (16%).

A catastrophic spill of a substance harmful to the ecosystem has not yet occurred in Polish marine areas. However, a serious accident, posing a real threat to the environment and human health and life, involving a ship carrying a chemical cargo occurred on January 1, 1979. Near Karwia, the Dutch chemical tanker m/s Anna Broere with a cargo of 2,400 tons of paraxylene was washed ashore. The successful operation to pull the vessel from the shoal took less than three weeks.

Environmental Decision	Decision on environmental conditions issued by the Regional Director for Environmental Protection in Gdańsk on July 7, 2016, ref. No. RDOŚ-Gd-WOO.4211.12.2015.KP.22, for the project named "Construction of the Bałtyk Środkowy III Offshore Wind Farm"
OWF BIII / Project	Bałtyk Środkowy III Offshore Wind Farm
NIS 2015	The most far-reaching scenario from the 2015 Report, which is a set of parameters of the project causing the most far-reaching impacts, and which was the basis for conducting the environmental impact assessment during the proceedings that ended with the issuance of the Environmental Decision
EIA	Environmental impact assessment
Report 2015	The Environmental Impact Assessment Report for the purposes of the procedure finalized by the decision of the Regional Directorate for Environmental Protection dated July 7, 2016, ref. No. RDOŚ-Gd-WOO.4211.12.2015.KP.22
Report / EIA Report	Environmental Impact Assessment Report of Bałtyk Środkowy III OWF
EIA Act	Act of October 3, 2008 on access to information on the environment and its protection, public participation in environmental protection and on environmental impact assessments (consolidated text, Journal of Laws of 2022, item 1029)

1. Introduction

This, Volume IV of the Report, contains the environmental impact assessment for the amendment of the environmental decision for the Baltic III offshore wind farm project. This volume fulfills the requirements of Article 66 (1) (2) and (3) of the EIA and constitutes an environmental impact analysis, with Volume II and Volume III of the Report as the basis for its execution.

For the preparation of this part of the EIA Report, the starting point was Volume IV of the Environmental Impact Report[1] which is the basis for the issuance of the current Environmental Decision[2]. The very nature of the proceedings being conducted, i.e. the amendment of the environmental decision, requires that it is the project assessed within the proceedings in the course of which the Environmental Decision was issued as the point of reference. This is because, unlike the standard environmental impact assessment procedure, in this case it is not the project itself that is being assessed, but the changes proposed to be made to the project before the investor began its implementation. Also, the assessment methodology in such a case must be adapted to the purpose of the proceedings, as the essence of the assessment is not to evaluate the environmental impact of the project, but to assess the impact of the proposed changes. The evaluation methodology used is described in Section 5 of Volume I of the Report.

In this volume, an analysis of the environmental impact of updating and refining the parameters of the Project in relation to the parameters of the Project under evaluation in the 2015 Report is presented. Due to the fact that the environmental assessment in the 2015 Report was carried out against a set of parameters causing the most far-reaching impacts called the furthest-reaching scenario - NIS 2015, and this assessment formed the basis for the acceptance of the parameters of the Project in the implementation variant from the 2015 Report, which was made in the Environmental Decision, therefore the analyses carried out in this volume refer to two sets of parameters of the Project, viz:

- parameters of the Project approved by the Environmental Decision, which is also the environmentally most favorable variant under the impact assessment conducted in the 2015 Report, consisting of no more than 120 offshore wind farms with associated infrastructure,
- parameters of the Project comprising the most far-reaching scenario - NIS 2015 - which assumed as one of the main parameters of the Project the location of no more than 200 power plants in the area of the farm, together with associated infrastructure.

The framework of the methodology was presented in Section 5 of Volume I, while the detailed conditions, conducting the assessment were carried over from the 2015 Report to ensure full comparability of the results of the conducted assessment.

In addition to the normal operation of the farm, the possibility of emergencies, including major accidents, and their potential impact on the environment were analyzed.

The content of Volume IV of the report fulfills the requirements of the provisions of the EIA indicated below.

According to Article 66 (1) (6) of the EIA, the report shall include a determination of the anticipated environmental impact of the analyzed variants, including in the event of a major industrial accident, as well as the possible transboundary environmental impact.

[1] Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

[2] Decision of the Regional Director of Environmental Protection in Gdansk RDOŚ-Gd-WOO.4211.12.2015.KSZ.22 dated March 7, 2016.

According to Article 66 (1) (7) of the EIA, the report shall include a justification of the variant proposed by the applicant, indicating its impact on the environment, in particular on:

- people, plants, animals, fungi and natural habitats, water and air,
- the earth's surface, including earth mass movements, and the landscape,
- material goods,
- monuments and cultural landscape, covered by existing documentation, in particular, a register or record of monuments,
- forms of nature protection, including on the goals and objects of protection of Natura 2000 areas, as well as the continuity of ecological corridors connecting them
- the interaction between the elements mentioned above,
- traffic safety for a road in the trans-European road network.

In accordance with Article 66 (1) (8) of the EIA, the report includes a description of the forecasting methods used by the applicant and a description of the anticipated significant environmental impacts of the planned project, including direct, indirect, secondary, cumulative, short-, medium- and long-term, permanent and temporary environmental impacts resulting from:

- existence of the venture,
- the use of environmental resources,
- emissions.

In addition, the information referred to in Article 66 (1) (4-8) shall take into account the anticipated impact of the analyzed variants on the objectives and object of protection of the Natura 2000 area and the integrity of the area.

Due to the very large number and variety of research and analysis results obtained, it was decided to divide Volume IV into sections in the form of stand-alone studies. Each of them is devoted to a different element of the environment and, in accordance with the above-mentioned requirements of Article 66 of the UoA, analyzes the impact of the BIII OWF on a particular element of the marine ecosystem:

- abiotic environment (including seabed, mineral resources, hydrological and hydrochemical conditions, physical and chemical conditions of sediments),
- bentos,
- fish,
- birds,
- marine mammals,
- bats,
- natura 2000 areas (included under individual sections)
- other protected areas and ecological corridors
- biodiversity

- climate
- cultural heritage,
- landscape,
- fishing,
- other users of maritime areas (including shipping, aviation).

The submitted Report, with respect to the 2015 Report, is supplemented with content that, due to a change in the regulations on the content of the environmental impact report, was not explicitly included and presented in separate chapters, particularly the sections related to impacts on climate and climate change and biodiversity.

A summary of the entire environmental impact assessment, gathering the results and conclusions of the sub-assessments, along with recommendations on the environmental conditions of the Project, is presented in Volume V.

1. Non-specialist summary

A non-specialist summary of the results of the assessment of the impact on the abiotic environment of the change in the conditions of implementation and operation of the Project - OWF BIII, for which the Environmental Decision was issued, is included in Section 5 of Volume VI of the Report.

2. Introduction

This section of the report assesses the potential impacts of updating and changing the conditions of implementation and operation of the Project - OWF BIII on the abiotic environment, i.e. the bottom with bottom sediments, marine waters and mineral deposits.

The assessment was carried out on the basis of the results of the performed environmental characterization (see Volume III of the Report with annexes of the EIA), the characteristics of the Project (see Volume II of the EIA), expert knowledge and analysis of industry literature. The assessment used the environmental impact assessment conducted in 2015 as part of the Report[1], on the basis of which the current environmental decision[2]was issued. Also used, discussed in the aforementioned 2015 Report, were models of suspended solids spreading, wave attenuation and changes in sea currents that may occur as a result of the Project. The assessment addresses changes in the project's implementation and operation conditions compared to the variant, which is the subject of the currently valid Environmental Decision, and analyzes whether they will potentially increase the previously identified impacts.

The abiotic elements of the marine environment, particularly water and sediment, are closely related. A change in one component (e.g., sediment) entails changes in another (e.g., water) and vice versa, so it is extremely important to consider the abiotic elements of the environment in conjunction with each other in an impact assessment. In addition, it should be borne in mind that sediments and waters are the habitat of living organisms, the functioning of which is very much dependent on the quality of sediments and waters, hence the assessment of the impact on the abiotic environment should also be considered as a starting point for analysis in terms of biotic elements of the environment.

3. Description of the planned project

3.1. Parameters of the BIII OWF relevant to the assessment of the impact of the project on the abiotic environment

The parameters of the BIII OWF that are relevant to the assessment of the project's impact on the abiotic environment are:

- farm location;
- area of the farm - total and buildable;
- foundations - types, number, dimensions and seabed area occupied by them, compaction, acoustic power of the pneumatic hammer used to drive pile foundations;

[1] Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

[2] Decision of the Regional Director of Environmental Protection in Gdansk RDOŚ-Gd-WOO.4211.12.2015.KP.22 dated July 7, 2016.

- power cables - their length and the surface of the bottom disturbed during their laying.

All of the above parameters, for the construction, operation and decommissioning phases of the Project, as well as their changes from the variant specified in the DWA, are presented and characterized in terms of potential emissions and environmental disturbances in Volume III of the Report.

3.2. Projects whose impacts may cumulate with those of OWF BIII on the abiotic environment

Information on existing, ongoing and planned projects, the impacts of which may cumulate with the impacts of the BIII OWF, causing their amplification, and the basic assumptions for the analysis of cumulative impacts of the planned farm are presented in Section 13 of Volume II of the Report.

In the area of OWF BIII, there were no existing, ongoing or planned projects for which an environmental decision has been issued that could potentially, together with OWF BIII, cause cumulative impacts on the abiotic environment.

4. Existing pressures anthropogenic

No significant anthropogenic pressures that could affect the abiotic environment have been recorded in the area of the proposed BIII OWF.

However, it should be remembered that the Baltic Sea is the body of water with the highest volume of shipping traffic in the world. The BIII offshore wind farm area is located outside the shipping lane, but in close proximity to it (TSS

- approximately 0.8 km to the south). More information on this topic of maritime transport and ship traffic in the area of the proposed OWF is included in Section 14 of Volume III of the Report.

There is seasonal fishing-related tourist traffic in the area. During the normal operation of ships, spills of various types of substances (diesel and lubricating oils, gasoline, etc.) may enter the water depths in small quantities, causing deterioration of water quality, which may have an indirect effect on sediments.

Commercial fishing by fishing boats is carried out in or near the study area. One form of fishing that affects sediment status is fishing trawling. This action can disrupt the structure of the sediment and promote the passage of metals and other harmful substances from the sediment into the water body, ultimately worsening water quality. However, the intensity of this measure is low, especially since, in general, fishery productivity (catch per area) in the area of the planned wind farm, as well as in its immediate vicinity, is low in relation to the average fishery productivity in Polish marine areas. The area also saw significantly lower-than-average fishing fleet activity. A detailed description of the fishery is presented in Section 13 of Volume III of this Report.

There are also no anthropogenic pressures in the analyzed area that could affect mineral resources - there are no mining activities related to exploration, prospecting and exploitation of deposits.

No other offshore activities were observed in the BIII OWF area that could affect seabed development, i.e.: nature conservation areas (based on the GDOŚ geoportal), cultural heritage areas, resource extraction areas, areas of military activities (no need to apply for survey permits), munitions dumping sites (HELCOM report), anchoring sites, flapping sites (i.e. sites for deposition of dredged material from dredging of port channels), according to the FMP.

5. Description of anticipated effects on the environment if the project is not undertaken project

This chapter analyzes the effects on the abiotic environment if the project is not undertaken. In doing so, three scenarios were considered:

- offshore wind energy will not be developed in the Polish maritime areas, and therefore the assessed project or one similar to it will not be implemented, nor will other activities such as the extraction of deposits;
- offshore wind energy will be developed in the Polish maritime areas, but the assessed project - BIII OWF - will not be implemented;
- in Polish maritime areas, investments in offshore wind energy are not being made, but the mining industry is developing.

The results of the analyses are shown in Table 1 below. Given that the Project has not been relocated, but only slightly reduced in scope, the effects of not undertaking it are the same as those discussed in the 2015 Report.

Table 1. Effects on the abiotic environment if the project is not undertaken

Lp.	Script	Environmental implications
1.	Offshore wind energy and mining industry will not grow	No action related to the construction, operation or decommissioning of offshore wind farms would mean no environmental impact. The area designated for OWF BIII will remain unchanged and will continue to be used as before (no change in the structure of the bottom surface, no navigational impediments, a larger fishing area). In the analyzed area, due to the normal operation of ships, spills of various types of substances (diesel and lubricating oils, gasoline, etc.) may enter the water depths in small quantities, causing deterioration of water quality and indirectly - sediments.
2.	Offshore wind energy will be developed, but OWF BIII will not be realized	From the point of view of impacts on the condition of bottom sediments and water quality, the type of sediments present at the planned OWF site is important. A greater impact involving greater redistribution of pollutants deposited in the sediment into the water body and the formation of greater long-lived suspended solids will be observed for clayey sediments (with a high content of organic matter and fine fractions), which are generally characterized by higher contents of metals, nutrients and organic pollutants. The least impact will occur when offshore wind farms are located in the area of coarse sands (with low organic matter and fine fractions), which are characterized by low levels of metals, nutrients and organic pollutants. Impacts will be observed in the area of planned investments. The area designated for OWF BIII will remain unchanged and will continue to be used as before (no change in the structure of the bottom surface, no navigational impediments, a larger fishing area). In the event that the BIII OWF is not built, but other wind farms are built in neighboring locations as a result of offshore wind energy development, no impact on mineral resources is expected in the BIII OWF area. It will be possible to explore, identify and extract potential deposits in the area. At the same time, however, with the establishment of farms on other sites, access to potential raw materials in these areas will be made much more difficult or impossible. This will reduce the South Baltic's raw material resources. Due to the lack of information on geological conditions and potential resource deposits in neighboring fields, it is impossible to

Lp.	Script	Environmental implications
		determine conclusively whether another location for the project would be more favorable.
3.	Offshore wind power will not develop, but mining industry will grow	If the mining industry develops, significant disturbance of the sediment structure will be observed. Depending on the type of sediment and the type of excavation work, a significant amount of metals, nutrients and organic or petroleum pollutants may be observed to pass into the water depths. The area designated for OWF BIII will remain unchanged and will continue to be used as before (no change in the structure of the bottom surface, no navigational impediments, a larger fishing area). If the mining industry is developed, the extraction of crumb raw materials in the study area will reduce the resource base of the South Baltic. At the same time, the area will be able to be surveyed for hydrocarbons. Other types of projects, such as fishing, shipping, will not affect raw materials in the BIII OWF area. They can only hinder the extraction of potential raw materials.

6. Methodology for assessing the impact on environmental

The impact assessment of the Project was conducted in accordance with the framework methodology adopted by the project, described in Section 5 of Volume I of the Report.

7. Potential impacts of offshore wind farms offshore wind farms

Information summarizing the most important emissions that the offshore wind farm may cause during the various stages of construction, operation and decommissioning, along with the identification of the type of emissions and impacts with a matrix of relationships, is presented in Section 7 of Volume II of the Report.

This chapter identifies the potential impacts of offshore wind farms on the abiotic environment at different stages of investment. The most important parameters and factors affecting the scale of impacts are also indicated. Since these are general data and information, regarding potential impacts of projects of this nature, independent of detailed solutions, the chapter directly refers to the description of impacts, which was presented in the 2015 Report.

7.1. Stage construction

Table 2. Potential impacts of the OWF on the abiotic environment - construction phase

Potential impact	Rationale for selection and key parameters and factors affecting the level of impact
Disruption of sediment structure	During the construction of the OWF, work will be carried out that will disturb the structure of the bottom sediments. These include, in particular, the installation of foundations and the laying of power cables. Such disturbances will also be caused by anchoring vessels.

Potential impact	Rationale for selection and key parameters and factors affecting the level of impact
	As a direct result of the disturbance of the bottom sediment structure, suspended solids will rise and dissolve in the water depths, and then be re-deposited on the bottom. The most important parameters affecting the level of impact are: • dimensions and number of foundations to be built and cables to be laid, • a type of rock material that forms the seabed.
Release of pollutants and nutrients from the sludge into the water body	Construction activities that disturb the sediment structure promote the passage of contaminants and nutrients from the sediment to the water body (Uścinowicz, 2011; Bojakowska, 2001; Frostner, 1980; Bourg and Loch, 1995; Dembska, 2003). Among other things, labile forms of metals, organic pollutants, i.e. polycyclic aromatic hydrocarbons (PAHs) and polychlorinated biphenyls (PCBs), biogenes (nitrogen and phosphorus compounds) will pass into the water. The most important parameters affecting the level of impact are: • dimensions and number of foundations, • the length of the cable sections and the width and depth of the cable trench, • the types and amount of pollutants deposited in bottom sediments, • a type of rock material that forms the seabed.
Change in the substrate composition of sediments	Some types of foundations, particularly gravity and monopiles, require layers of leaching protection around their bases. It will also depend on the materials that make up the seabed. For this purpose, rock ballast, stones and boulders are most often used. In addition, during the foundation of gravity foundations, it is necessary to replace the subsoil with soil of higher bearing capacity. Rock ballast or gravel is also usually used for this purpose. These activities change the substrate composition of bottom sediments. The most important parameters affecting the level of impact are: • types, dimensions and number of foundations, • a type of rock material that forms the seabed.
Disruption of the bottom structure	During the construction of the OWF, work will be carried out that will disturb the bottom structure. These include, in particular, the need to properly prepare the bottom before laying the foundation, drilling or driving foundations, locating towers, installing support structures (monopiles and piles of jacket and tripod foundations to depths of several tens of meters), laying or possibly burying cables, dredging work, and dumping rock material. The most important parameters affecting the level of impact are: • types, dimensions and number of foundations, • a type of rock material that forms the seabed.

Potential impact	Rationale for selection and key parameters and factors affecting the level of impact
Change in bottom morphology	The foundation of wind farm elements is associated with a change in the morphology (shape) of the bottom. Changes in the morphology of the bottom will also occur as a result of possible storage of excavated rock from the preparation of the bottom for foundations (primarily gravity). The most important parameters affecting the level of impact are: • types, dimensions and number of foundations, • a type of rock material that forms the seabed.
Ground settlement	Depending on the mass, the foundation can cause soil compaction, that is, compaction due to a reduction in the number of free spaces between sediment grains, resulting in settlement. The most important parameters affecting the level of impact are: • types, dimensions, weight and number of foundations, • a type of rock material that forms the seabed.
Occupation of the seabed area	Foundations and cables belonging to the OWF occupy certain areas of the seabed. During the construction phase, the area of occupied bottom will gradually increase. The most important parameters affecting the level of impact are the diameter of the base and the number of foundations, as well as the length of the cable.
Use of sand as foundation ballast	Dredged material for the foundation is often used as ballast for a gravity foundation, provided it is sandy sediment (Peire et al., 2009). This can lead to a loss of reservoir properties (reduction of surface area, separation of the reservoir field). Identical applications can be found in sand deposits. The most important parameters affecting the level of impact are the type of foundation (will only occur with gravity foundations) and their number.
Washing out, stripping or burying mineral deposits	During the construction of the OWF, works are carried out that cause disturbance to the structure and morphology of the seabed. Sediment movement in the bottom zone may also be disturbed during the construction phase. The constructed foundations of the power plant are an obstacle to the displaced sediment. As a result, this can lead to the accumulation and/or leaching of sediment, resulting in the leaching of bed deposits or their backfilling. The most important parameters affecting the level of impact are the diameter of the base and the number of foundations to be built, as well as the length of cables to be laid.
Impediment to access to mineral deposits	Foundations and cables belonging to the OWF occupy certain areas of the seabed, hindering possible exploration and extraction of mineral resources. The most important parameters affecting the level of impact are the diameter of the base and the number of foundations being built. The foundation that occupies the largest bottom area is the gravity foundation. This foundation also requires additional bottom preparation. Some of the raw sediment may be excavated when

Potential impact	Rationale for selection and key parameters and factors affecting the level of impact
	preparing the ground for foundations. Other types of foundations, despite occupying a smaller area of the bottom, can make mining and resource exploration difficult or impossible (James McElfish, Adam Schempp, and Jordan Diamond, 2013).
Pollution of water bodies and bottom sediments with petroleum substances	At each stage of the project, vessels (ships, barges, etc.) will be used, from which small spills of petroleum substances (lubricating and diesel oils, gasoline, etc.) into the water depths may occur during normal operation. Pollution entering the water's depths during normal ship operations is the second largest source of oil pollution at sea. From this source, about 33% of the oil entering the environment enters the waterways (mainly due to increased ship traffic in the Baltic Sea region (Kaptur, 1999). In comparison, about 37% of the oil that enters the sea comes from river runoff from land, and only in third place are tanker disasters (12%). Release of petroleum substances can also occur in emergency situations (ship failure or collision, power substation failure, construction disaster). Heavier oil fractions can be sorbed on the surface of organic and mineral suspensions, which will cause their specific gravity to increase and gradually sink to the bottom. There they can be bound by bottom sediments. The most important parameters affecting the level of impact are: • the type and aterial of rock forming the seabed.
Contamination of water depths and bottom sediments with antifouling agents	At each stage of the project, vessels (ships, barges, etc.) will be used, from whose hulls some amounts of antifouling substances may be released into the water depths during normal operation. They can then contaminate the sediments. The most important parameters affecting the level of impact are: • the type and amount of antifouling substances released, • a type of rock material that forms the seabed.
Contamination of water bodies and bottom sediments with accidentally released municipal waste or domestic sewage	At each stage of the project, on the vessels as well as at the construction facilities located on land (at the port serving the implementation of the project), waste will be generated, mainly municipal and other waste not directly related to the construction process, as well as domestic sewage. Waste and wastewater can be accidentally released into the sea when picked up from ships by another vessel and in the event of an accident. The most important parameters affecting the level of impact are: • the type and amount of waste or wastewater released, • weather conditions, • a type of rock material that forms the seabed.
Contamination of water bodies and bottom sediments with accidentally released chemicals and waste from the construction of the farm	During the construction of the wind farm, waste directly related to the construction process will be generated on vessels, at the construction facilities located onshore (at the port serving the project) and at the project site. These can include damaged parts of the farm's assembled components, cement, grout, mortar, binders used to join the

Potential impact	Rationale for selection and key parameters and factors affecting the level of impact
	foundation and power plant components, and other chemicals used during construction work. They can be accidentally released accidentally into the sea. The most important parameters affecting the level of impact are: • the type and amount of waste or wastewater released, • weather conditions, • a type of rock material that forms the seabed.
Changes in the regime of sea currents	The foundation structures built during the construction of the farm may cause changes in the regime of sea currents. The most important parameters affecting the level of impact are the dimensions, number and density of foundations.
Wind wave attenuation	The foundation structures built during the construction of the farm may cause wind wave attenuation. The most important parameters affecting the level of impact are the dimensions, number and density of foundations.
Increase in water turbidity	Construction work will disrupt the structure of bottom sediments and raise suspended solids, resulting in an increase in water turbidity. The most important parameters affecting the level of impact are: • the type, dimensions and number of foundations, • the length of the cable sections and the width and depth of the cable trench, • the types and amount of pollutants deposited in bottom sediments, • a type of rock material that forms the seabed.

7.2. Stage operation

Table 3. Potential impacts of the OWF on the abiotic environment - operation stage

Potential impact	Rationale for selection and key parameters and factors affecting the level of impact
Disruption of sediment structure	During the operation of the OWF, work will be carried out to disturb the structure of the bottom sediments, such as replacing damaged sections of the power cable. Disturbance will also be caused by anchoring vessels. In addition, the bottom sediments in the immediate vicinity of the foundation structures will be washed out. To prevent this from happening, leaching protection will be used. The most important parameters affecting the level of impact are: • dimensions and number of foundations, • a type of rock material that forms the seabed.

Potential impact	Rationale for selection and key parameters and factors affecting the level of impact
Release of pollutants and nutrients from the sludge into the water body	Maintenance work that disrupts the sediment structure promotes the passage of pollutants and nutrients from the sediment into the water body. The leaching of bottom sediments in the immediate vicinity of the foundations will have a similar effect. Labile forms of metals, organic pollutants, i.e. polycyclic aromatic hydrocarbons (PAHs) and polychlorinated biphenyls (PCBs), biogenes (nitrogen and phosphorus) can pass into the water. The most important parameters affecting the level of impact are: • dimensions and number of foundations, • the types and amount of pollutants deposited in bottom sediments, • a type of rock material that forms the seabed.
Change in the substrate composition of sediments	Some types of foundations, particularly gravity and monopiles, require layers of leaching protection around their bases. It will also depend on the materials that make up the seabed. For this purpose, rock ballast, stones and boulders are most often used. These activities change the substrate composition of bottom sediments. The most important parameters affecting the level of impact are: • types, dimensions and number of foundations, • a type of rock material that forms the seabed.
Disruption of the bottom structure	Disturbance of the bottom structure, which was created at the stage of construction work, for example, due to the driving of foundation piles or the replacement of the sediment layer with gravel, will be permanent, and thus will exist throughout the life of the farm. No additional work (drilling, hammering) is expected to take place during this time, so the scale of this impact will not increase. The most important parameters affecting the level of impact are: • types, dimensions and number of foundations, • a type of rock material that forms the seabed.
Change in bottom morphology	The foundation of wind farm components involves a change in the shape of the bottom. Changes in bottom morphology will also occur during the operational stage. There may be changes in the geological processes of the seabed at wind turbine foundation sites. Locally, erosion may occur - foundation washout or sediment accumulation in the vicinity of foundations. The most important parameters affecting the level of impact are: • types, dimensions and number of foundations, • a type of rock material that forms the seabed.
Ground settlement	Depending on the mass, the foundation can cause soil compaction, that is, compaction due to a reduction in the number of free spaces between sediment grains, resulting in settlement. This phenomenon will also occur at the operational stage, especially if heavy gravity foundations are used. The most important parameters affecting the level of impact are: • types, dimensions, weight and number of foundations,

Potential impact	Rationale for selection and key parameters and factors affecting the level of impact
	• a type of rock material that forms the seabed.
Occupation of the seabed area	Foundations and cables belonging to the OWF occupy certain areas of the seabed. The occupation of the bottom will continue throughout the life of the farm. The most important parameters affecting the level of impact are the diameter of the base and the number of foundations.
Washing out or burying mineral deposits	During the operation stage, sediment movement in the bottom zone may be disturbed. The constructed foundations of the power plant are an obstacle to the displaced sediment. As a result, this can lead to the accumulation and/or leaching of sediment, resulting in the leaching of bed deposits or their backfilling. The most important parameters affecting the level of impact are the diameter of the base and the number of foundations.
Impediment to access to mineral deposits	Foundations and cables belonging to the OWF occupy certain areas of the seabed, hindering possible exploration and extraction of mineral resources. The most important parameters affecting the level of impact are the diameter of the base and the number of foundations.
Pollution of water bodies and bottom sediments with petroleum substances	See description for construction phase
Contamination of water depths and bottom sediments with antifouling agents	See description for construction phase
Contamination of water bodies and bottom sediments with accidentally released municipal waste or domestic sewage	See description for construction phase
Contamination of water bodies and bottom sediments with accidentally released chemicals and waste from the operation of the farm	During the operation of the wind farm, waste directly related to the operation of the wind farm will be generated on vessels, at the construction facilities located onshore (at the port serving the project) and at the project site. These may include damaged parts of farm components, cement, grout, mortar, operating fluids and other chemicals used or replaced during maintenance work. They can be accidentally released into the sea. The most important parameters affecting the level of impact are: • the type and amount of waste or wastewater released, • weather conditions, • a type of rock material that forms the seabed.
Pollution of water bodies and bottom sediments with compounds from corrosion protection agents	Steel foundation structures require the use of corrosion protection. The most common anti-corrosion method used in the marine environment is cathodic protection. It can be implemented as galvanic or electrolytic protection. Galvanic cathodic protection involves installing aluminum or zinc anodes on the foundations. Anodes are gradually consumed and Al or Zn passes into the water depths and accumulates in bottom sediments.

Potential impact	Rationale for selection and key parameters and factors affecting the level of impact
	In electrolytic cathodic protection, the protected object becomes the cathode of an electrolytic cell supplied with DC current from an external source. The anode used in this circuit is mostly insoluble. Among the most durable anode materials used in this method are platinum and titanium electrodes coated with a 2-3 µm layer of platinum. With electrolytic cathodic protection, no impact on water quality or sediment is observed. The most important parameters affecting the level of impact are: • the type and amount of elements released, • water quality in the project area, • a type of rock material that forms the seabed.
Change in water and sediment temperature	The electric current, flowing through the power cable, causes it to heat up, caused by power losses on the resistance, according to Joule's law. As the temperature of the cable rises above ambient temperature, heat transfer to the surrounding environment begins. Raising the temperature of the sediment in which the cable is buried and the interstitial waters can cause: • increased bacterial activity, resulting in accelerated decomposition of organic matter, • a reduction in the oxygen content of the water, • release of harmful substances, including metals, from the sediment into the water's surface, • adverse effects on benthic organisms. The most important parameters affecting the level of impact are: • depth of cable burial, • a type of rock material that forms the seabed.
Changes in the regime of sea currents	The foundation structures of individual farm facilities may cause changes in the regime of sea currents. The most important parameters affecting the level of impact are the dimensions, number and density of foundations.
Wind wave attenuation	The foundation structures of individual farm facilities may cause wind wave attenuation. The most important parameters affecting the level of impact are the dimensions, number and density of foundations.
Increase in water turbidity	Some maintenance work (e.g., replacing a damaged section of cable), as well as anchoring ships, will disturb the structure of bottom sediments and raise suspended solids, resulting in an increase in water turbidity. The most important parameters affecting the level of impact are: • the volume of disturbed bottom sediments, • the types and amount of pollutants deposited in bottom sediments, • a type of rock material that forms the seabed.

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

7.3. Stage decommissioning

Table 4. Potential impacts of the OWF on the abiotic environment - decommissioning stage

Potential impact	Rationale for selection and key parameters and factors affecting the level of impact
Disruption of sediment structure	During the decommissioning of the OWF, work will be carried out that will disturb the structure of the bottom sediments. These include, in particular, dismantling foundations and removing power cables. Such disturbances will also be caused by anchoring vessels. As a direct result of the disturbance of the bottom sediment structure, suspended solids will rise and dissolve in the water depths, and then be re-deposited on the bottom. The most important parameters affecting the level of impact are: • types, dimensions and number of foundations, • a type of rock material that forms the seabed.
Release of pollutants and nutrients from the sludge into the water body	During the decommissioning of the OWF, work will be carried out that causes agitation of bottom sediments, such as the removal of foundations, cables and anchoring of ships. They will favor the passage of pollutants and nutrients from the sediment into the water body. Labile forms of metals, organic pollutants, i.e. polycyclic aromatic hydrocarbons (PAHs) and polychlorinated biphenyls (PCBs), biogenes (nitrogen and phosphorus) can pass into the water. The most important parameters affecting the level of impact are: • the dimensions and number of decommissioned foundations and the length of cables, • the types and amount of pollutants deposited in bottom sediments, • a type of rock material that forms the seabed.
Disorders of the structure of the fundus	Disturbances to the bottom structure that occurred during the construction phase, such as from the driving of foundation piles, will be permanent, so they will also exist during and after the decommissioning of the farm. The most important parameters affecting the level of impact are: • types, dimensions and number of foundations, • a type of rock material that forms the seabed.
Change in bottom morphology	The effect of removing foundations or cables, or leaving some elements of the farm in the seabed will be changes in its morphology (such as foundation holes). The most important parameters affecting the level of impact are: • types, dimensions and number of foundations, • a type of rock material that forms the seabed.
Occupation of the seabed area	Foundations and cables (if left on the seabed during the decommissioning of the farm), will occupy permanently defined areas of the seabed. The most important parameters affecting the scale of the impact are the diameter of the base and the number of foundations, as well as the length of the cables.

Potential impact	Rationale for selection and key parameters and factors affecting the level of impact
Washing out or burying mineral deposits	During the decommissioning of the OWF, work is carried out on dismantling the various elements of the farm, causing disruption to the structure and morphology of the seabed. They can cause the deposits of crumb raw materials to be washed out or buried. The most important parameters affecting the scale of the impact are the diameter of the base and the number of foundations being eliminated.
Impediment to access to mineral deposits	Foundations and cables (if left on the bottom during the decommissioning of the farm), will permanently obstruct access to raw material deposits. The most important parameters affecting the scale of the impact are the diameter of the base and the number of foundations, as well as the length of the cables.
Pollution of water bodies and bottom sediments with petroleum substances	See description for construction phase
Contamination of water depths and bottom sediments with antifouling agents	See description for construction phase
Contamination of water bodies and bottom sediments with accidentally released municipal waste or domestic sewage	See description for construction phase
Contamination of water bodies and bottom sediments with accidentally released chemicals and waste from the decommissioning of the farm	During the decommissioning of the wind farm, waste directly related to the decommissioning of the wind farm will be generated on vessels, at the construction facilities located onshore (at the port serving the project) and at the project site. These may include damaged parts of farm components, operating fluids, etc. They can be accidentally released accidentally into the sea. The most important parameters affecting the level of impact are: • the type and amount of waste or wastewater released, • weather conditions, • a type of rock material that forms the seabed.
Changes in the regime of sea currents	The foundation structures of individual farm facilities (if left on the bottom during decommissioning of the farm) may cause changes in the regime of sea currents. The most important parameters affecting the level of impact are the dimensions, number and density of foundations.
Wind wave attenuation	The foundation structures of individual farm facilities (provided they are left in the seabed during decommissioning of the farm) may cause wind wave attenuation. The most important parameters affecting the level of impact are the dimensions, number and density of foundations.
Increase in water turbidity	Maintenance work (e.g., removing foundations and cables from the bottom), as well as anchoring ships, will disturb the structure of bottom

Potential impact	Rationale for selection and key parameters and factors affecting the level of impact
	sediments and raise suspended solids, resulting in an increase in water turbidity. The most important parameters affecting the level of impact are: • the volume of disturbed bottom sediments, • the types and amount of pollutants deposited in bottom sediments, • a type of rock material that forms the seabed.

8. Receptors subject to environmental impact assessment environment

As with Section 7 of this volume, since information on potential receptors of impacts is specific to the type of offshore wind farm projects and is independent of detailed solutions, the chapter directly cites the description that was provided in the 2015 Report.

8.1. Basic characteristics of abiotic environmental resources in the area of the proposed farm

The abiotic environmental resources (receptors) assessed in the Report are the seabed, bottom sediments, marine waters and mineral deposits in the area of the proposed project. Surveys of these resources were conducted by the Maritime Institute in Gdansk, and detailed descriptions and their current status are presented in Sections 2 - 5 of Volume III of the Report.

In the seabed survey report, the farm area was divided into five sub-areas (P1 - P5) with different structure, seabed sediment genesis and structure, which will be addressed by the impact assessment performed and presented below (see Sections 3 and 5 of Volume III of the EIA).

8.2. Sensitivity of abiotic environmental resources to potential impacts project

The sensitivity of individual receptors to the impacts of offshore wind farms during the construction, operation and decommissioning stages is shown in the tables below.

The sensitivity/susceptibility of a given receptor to IMF impacts is understood as a function of the resource's ability to adapt to the potential change resulting from the project and its ability to return to baseline.

Table 5. Vulnerability (sensitivity) of abiotic receptors to OWF impacts - construction phase

8.3. The importance of abiotic resources of the environment

Water as well as bottom sediments are very important elements of the aquatic ecosystem of the Baltic Sea, which is a shallow and small sea with limited water exchange through the narrow and shallow Danish Straits. The surface area of the sea is about four times smaller than its catchment area. About 85 million people live in the area. Such conditions mean that any interference with the marine environment - fishing, shipping, discharge of municipal and industrial wastewater, surface runoff from industrialized and agricultural areas, but also bottom mining and development activities - affects the delicate ecological balance of the sea (Uscinovich, 2011). Water and sediment in water bodies are closely related. There is a kind of state of equilibrium between the various components of the marine environment, especially between water and bottom sediment. A change in one component (e.g., sediment) entails changes in another (e.g., water) and vice versa.

Most of the pollutants (heavy metals and toxic organic compounds with low solubility and difficult to degrade) released into the environment as a result of human economic activities and reaching surface waters are retained in sediments (Bojakowska, 2001). However, sediments are not only the main repository of persistent and toxic pollutants entering the environment, but also the habitat, nutrition, reproduction and growth of many aquatic organisms. Contaminated aquatic sediments pose a major threat to the biosphere, since some of the harmful components contained in the sediments can pass into the water through chemical and biochemical processes and be available to living organisms (Frostner, 1995; Bourg and Loch, 1995). In addition, the movement of contaminated sediments, whether natural or man-made (transport, dredging, local turbulence, etc.) or rising temperatures, can cause them to move to higher water layers, where open water organisms will also be exposed to contaminants. The above relationships between abiotic and biotic elements of the environment are discussed in Section 10 (Related Impacts).

In determining (according to the methodology) the importance of a given receptor (resource) was taken into account:

- the baseline condition of the resource found in environmental studies,
- is that none of the resources are subject to legal protection,
- their susceptibility (sensitivity) to the impacts of the farm.

The assumed importance of each resource is shown in the table below.

Table 8. Identify the importance of abiotic receptors/resources for ecosystem functioning

Receptor	The importance of the receptor (resource)
Seabed with sediments (areas P1 and P3)	Large
Seabed with sediments (areas P2, P4 and P5)	Medium
Marine waters	Medium
Gravelly sand deposits	Medium
Hydrocarbon deposits	Small

9. Assessment of the impact of OWF BIII on abiotic resources environment

This chapter evaluates the variant of the project that will be implemented on the basis of the Environmental Decision, amended in accordance with this application.

9.1. Stage construction

During the construction of the BIII OWF, works will be carried out that affect the seabed and seawater in the project area, the most significant of which are:

- drilling performed during geotechnical studies;
- preparation of the bottom prior to the installation of the foundation, including dredging of the bottom, removal of the sediment layer with a thickness of about 2 - 3 m and replacing it with rock material with a higher bearing capacity (only in the case of gravity foundations, which can be used in the currently proposed variant of the Project only for supporting infrastructure);
- drilling or driving foundations (only in the case of monopiles, jacket or tripod foundations, while in the currently requested variant of the Project tripod foundations can be used only for supporting infrastructure);
- anchoring jack - up platforms and support units during the assembly of farm components;
- burying cables in the seabed;
- heaping of rock material serving as protection against leaching;
- storage of excavated material from the preparation of the bottom for foundations.

A full description of the construction work can be found in Section 4 of Volume II of the EIA.

The following impacts of OWF BIII on the abiotic environment are expected at the construction stage:

- disruption of sediment structure;
- the release of pollutants and nutrients from the sediment into the water body;
- changing the substrate composition of sediments;
- disruption of the bottom structure;

- change in bottom morphology;
- ground settlement;
- seabed area occupation;
- washing out, picking out or burying accumulations of mineral resources;
- making access to mineral accumulations more difficult;
- changing the regime of sea currents;
- wind wave attenuation;
- water turbidity.

There may also be unplanned impacts during the construction of the farm, particularly contamination of the water table and bottom sediments:

1) petroleum substances,
2) antifouling agents,
3) accidentally released municipal waste or domestic sewage,
4) accidentally released chemicals and waste from the construction of the farm.

Unplanned impacts are described in detail in Section 12 of Volume II of the Report and in Chapter 11 of this section.

9.1.1. Disruption of the structure of sediments

During the construction of offshore wind farm BIII, there will be works that cause local disturbance of the structure of the bottom sediments. These include, in particular, the installation of foundations and the laying of power cables. Disturbance will also be caused by anchoring vessels and driving the legs of ships and jack - up barges into the seabed to stabilize their position. The predicted level of sediment agitation and redeposition and the conditions adopted for the analysis are described in detail in Section 4 of Volume II of the Report.

As a direct result of the disturbance of the bottom sediment structure, suspended solids will rise and spread (resuspension) in the water depths and be re-deposited on the bottom. The dredging of sediment during wind farm construction depends primarily on the volume of sediment moved during the work (for example, single-pile foundations do not require any dredging). The choice of gravity foundations assumed in the 2015 NIS, which formed the basis for conducting the assessment in the 2015 Report, would have resulted in an increase in the volume of sediment removed by dredging, thereby increasing the rate of sediment lift,

The 2015 Report estimated that the agitated sediment would move primarily within the farm area and up to a dozen kilometers from the farm boundaries, and falling over most of the area would cover the bottom to an average thickness of about 0.2 - to about 0.4 mm (see Section 4 of Volume II of the EIA).

However, in the variant selected` for implementation, this type of foundation is considered only for associated infrastructure, which will significantly reduce the negative impact on the sediment structure. As a consequence of the proposed changes to the Project, the use of gravity foundations for power plants has been excluded (foundations have been limited to monopile or jacket foundations), the number of foundations has been reduced to 60 for power plants (compared to the 120 provided for in

the Environmental Decision and 200 in the 2015 NIS), and the number of supporting infrastructure elements has been reduced from 6 pieces to one. The proposed change in conditions for the Project will have a significant impact on the magnitude of impacts associated with the disturbance of sediment structure.

Some heavy metals, pollutants and nutrients will be released from the bottom sediments as a result of the agitation, as discussed in detail in the next section. There will also be a temporary turbidity of the water.

Aggradation of bottom sediments can also affect potential deposits of crumb raw materials. It can lead to the leaching or extraction of raw materials during foundation preparation or cover them with an additional layer of sediment from the excavated material, making it impossible to extract them, by increasing the thickness of the overburden above the deposit.

There may also be a disturbance of sediment movement in the bottom zone. The successively rising foundations of the power plant will be an obstacle to the displaced sediment, leading to the accumulation and/or leaching of sediment, as well as - the leaching of bed sediment or its backfilling.

The most important technical parameters affecting the level of impact are the dimensions and number of foundations. The greatest impact on sediment would occur if the ground for gravity foundations with the maximum expected base diameter, i.e. 40 m, along with a leaching protection layer (the basis of the assessment in the 2015 Report, the most far-reaching scenario - NIS 2015). However, the variant that is the subject of the amendment to the Environmental Decision does not provide for gravity foundations under the turbines, but only under elements of supporting infrastructure, so the impact will be limited compared to that assessed in the 2015 Report.

Laying cables, on the other hand, involves plowing the bottom or washing out the sediment with a high-pressure water jet to create a cable trench.

The type of rock material forming the seabed will also affect the level of impact (see Section 3 of Volume III of the EIA).

Areas P1 and P3, located in the northern and northwestern parts of OWF BIII, are outcrops of glacial till with a variable sand and gravel cover, where there is no loose sediment on the surface or the layer is thin, and with numerous pebbles on the surface. A compact deposit such as clay is difficult to dilute under natural conditions. Due to the discontinuous layer of sands and gravels of variable thickness and the compact structure of the clay, the susceptibility to agitation of the surface sediment is low. Disturbance of the sediment structure will be of little importance here, even if large gravity foundations are used.

Areas P2 and P5 (silty-muddy sediments with a thick cover of sandy sediments), as well as area P4 (glacial till covered by a layer of sandy sediments with single boulders on the surface), in the central, eastern and southwestern parts of the farm, constitute a substrate that is not very stable, so it is necessary to replace it before the foundation of gravity foundations. Suspension (resuspension) of greater intensity may be triggered in these areas.

At the same time, the disturbance of bottom sediments can slightly improve their quality (increasing oxygenation and reducing the amount of pollutants and nitrogen compounds in the sediment due to their transition to the water tone). Better oxygenation of the sediment, on the other hand, can reduce (limit) the passage of phosphorus from the sediment, since this process occurs under anaerobic (reducing) conditions (Alloway and Ayres, 1999).

Due to the lack of significant impacts, minimization measures are not required, while the planned use of monopal or jacket foundations will significantly reduce the scale of impacts.

Violation of bottom sediment structure, is a direct, negative impact during the construction phase that is local in scope, short-term, reversible, repeatable during the construction period, with intensity ranging from low (areas P1 and P3) to medium or high (areas P2, P4 and P5).

The 2015 Report, the basis for the issuance of the current Environmental Decision, assessed the significance of this impact for the most far-reaching scenario, as quoted below in Table 9, with the impacts for the variant approved by the Environmental Decision assessed as lower.

Table 9. Impact assessment involving disturbance of bottom sediment structure (construction phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Seabed / bottom sediments	Large (areas P1 and P3)	Low (areas P1 and P3)	During the construction of the farm, the structure of the bottom sediments will be disturbed	Negligible (scale of exposure - local, duration - short-term, intensity - low)	Small (magnitude of impact - insignificant, importance of the resource - high)
	Medium (areas P2, P4 and P5)	Medium (areas P2 and P4) or high (area P5)		Negligible (scale of exposure - local, duration - short-term, intensity - medium to high)	Negligible (magnitude of impact - insignificant, Importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

In summary, the variant that is the subject of this Report will build about 70% fewer foundations than envisioned in the 2015 NIS and twice as many as specified in the Environmental Decision, it also excludes the use of gravity foundations under the power plants and reduces the number of foundations for supporting infrastructure to one unit with a slight increase in the unit area of one. As a result, violations of the bottom sediment structure will occur over a much smaller area. It is therefore considered that the project will cause significantly lower impacts than both those assessed for the 2015 NIS and the variant approved in the DWA.

Thus, it should be considered that both the nature of the impacts does not change and their scope and intensity are significantly smaller than in the case of the variant approved by the Environmental Decision, and thus the proposed change in the parameters of implementation and operation of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.1.2. Release of pollutants and nutrients from the sludge into the water body water

Agitation (disturbance) of the bottom sediment associated with the construction (foundation) of foundations for farm facilities, anchoring ships or burying cable is a process that promotes the passage of contaminants from the sediment to the water depths (Uścinowicz, 2011; Bojakowska, 2001; Frostner, 1980; Bourg and Loch, 1995; Dembska, 2003). This way they can get to it:

- pollutants, including heavy metals and PAHs and PCBs;
- biogenic elements - nitrogen and phosphorus.

Detailed assumptions and analysis of predicted sediment emission levels are described in detail in Section 4 of Volume II of the Report.

The phenomenon of depletion of the surface layer of sediment in areas of sediment agitation is confirmed by scientific studies. This process was observed by Bolalek and Pustelnikovas (1995) at Klaipeda Port at the site where hydrofoils and ships turn back, as well as Protasowicki et al. (1992), studying the bottom sediments of the fairway in the Szczecin Lagoon.

The intensity and effects of the processes described will depend on:

- sediment type (grain size);
- the content of pollutants and nutrients in sediments;
- the type of foundation chosen.

Sediment types in the study area vary from location to location. In the seabed survey report, the farm area was divided into five sub-areas (P1 - P5) with different structures and origins (see Section 3 and Section 5 of Volume III of the EIA).

The most unfavorable situation (see Section 4 of Volume II of the EIA) may occur in the case of sludge characterized by an elevated content of noxious substances and nutrients and a large amount of fine fractions (clay and silt fractions). In this case, there may be a significant deterioration of water quality due to an increase in the concentration of harmful and biogenic substances (due to the passage from the sediment to the water body as a result of sediment uplift processes). These sediments will also promote the formation of more suspended solids, which will persist in the water depths for a long time. Intense resuspension can cause the release of nutrients immobilized in the sediment and contribute to eutrophication. In the case of sandy sediments with low organic matter content (e.g., coarse-grained sandy sediments), the processes described will be less intense. These sludges are generally characterized by small amounts of fine fractions and low concentrations of metals and persistent organic pollutants. Accordingly, it is estimated that the processes associated with the release of nutrients will occur with low intensity in P1 and P3 areas and with much higher intensity in P2, P4 and P5 areas.

The content of pollutants and nutrients in the collected bottom sediments from the BIII offshore wind farm area does not differ from the average concentrations of these substances in the bottom sediments of the South Baltic. This issue is discussed in detail in Section 5 of Volume III.

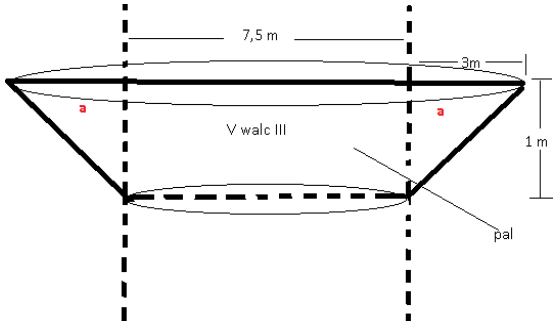
The type of foundations that will eventually be used on the farm will affect the amount of pollutants and nutrients released during construction, due to the different volumes of bottom sediments that will be stirred up during their installation. The basic technical parameters of the foundations are described in Section 3 of Volume III.

The most far-reaching scenario that forms the basis for conducting the assessment in the 2015 Report, is the use of gravity foundations (NIS 2015). Their construction would require the preparation of the bottom, which would involve the removal of a layer of bottom sediments, not only at the foundation site, but also in its immediate vicinity.

In the case of the technologies currently under consideration (the variant chosen for implementation - monopal or jacket), the volume of disturbed sediment will be many times smaller, which is related to the fact that they do not require bottom preparation in most cases, as well as the fact that the diameter of the driven foundation piles will be many times smaller than the diameter of the gravity foundation. The sediment around the driven piles will liquefy due to the vibrations caused by the operation of the jackhammer. The following is an example calculation of the amount of shaken sludge for a monopile with a diameter of 10 m (the maximum diameter of the monopile).

Assuming that piles with a diameter of 10 meters (i.e., a radius of 5 meters) will be driven into the bottom at a depth of several tens of meters, it can be assumed that sediment at a depth of about 1.5 meters and in a radius of about 3 meters around the pile Figure 1, below, shows in a very simplified (illustrative) manner that part of the sediment that may be moved, which would result in the passage of contaminants and nutrients from the sediment to the water depth, during the driving of the pile into the bottom.

Figure 1. Schematic diagram of how to determine the sediment stirred up during pile driving at the bottom



7,5 m	7,5 m
V walc III	V waltz III
pal	pal

The volume of sediment to be stirred up when the pile is driven into the seabed was calculated from the formula below:

$$_{Va_=}$$ V st ¶c.-V val.III,

where:

$_{Va}$ - the volume of the sediment layer that is stirred up when the pile is driven into the seabed,
V st ¶c. - volume of a truncated cone,
V cylinder III- volume of cylinder III

After substituting the data into the formula, the volume of sediment to be stirred up during the driving of one pile into the seabed is about 78.5$^{m3\ of}$ sediment per foundation (monopile).

In addition, regardless of the type of foundation chosen, the sediment will be stirred up when the cable is laid. The width of the cable trench is about 1.5 meters, the average depth is up to 1.5 meters, and the length is up to 200 kilometers, making a total of 450,000$^{m3\ of}$ shaken sediment (for the entire internal cable network).

In addition, the stirring of bottom sediment associated with ship anchoring will be observed during foundation placement and tower installation. The anchoring process itself is short-lived, in a small area (spot), at a depth of about 3 meters, so the volume of disturbed sediment will also be small.

Based on the above assumptions and the concentrations of pollutants and nutrients found in the area of the farms (see Section 5 of Volume III of the EIA), the 2015 Report made an estimate of their emissions to the water body in the most far-reaching scenario (NIS 2015), which may occur due to the construction of 200 foundations (Table 10). The calculations assumed an average volumetric density of the sludge of 1.52 $^{g/cm3}$ (1520 $^{kg/m3}$) and an average sludge moisture content of 17.7%.

Table 10. Estimated maximum emissions of pollutants from agitated sediments for the furthest-reaching scenario (NIS 2015) of OWF BIII

Pollution	Estimated maximum value of emissions from sludge
	NIS [kg]
lead (Pb)	3274 kg
copper (Cu)	1592 kg
chromium (Cr)	2,373 kg
nickel (Ni)	1592 kg
zinc (Zn)	8,291 kg
cadmium (Cd)	Concentration in the area below the limit of quantification
mercury (Hg)	Concentration in the area below quantification
pCB group congeners	1.5 g - 57 g
pAH group analytes	150 g - 12917 kg
assimilable phosphorus (P)	159.2 Mg

The volumes of pollutant emissions that may be released during construction will be negligible, compared to the loads carried into the Baltic Sea annually from rivers and wet precipitation (Uścinowicz, 2011), which does not significantly affect water quality.

No measures are envisaged to minimize impacts in the form of the release of pollutants and nutrients from stirred up bottom sediments.

The processes associated with the construction (foundation) of the foundations for the towers may result in better oxygenation of the sediments, and thus increase the intensity of nitrification processes and multiply the release of nitrates into the water table. It can also upset the overall pattern of the nitrogen cycle by reducing the intensity of denitrification processes that occur under anaerobic conditions and involve the conversion of nitrate to molecular nitrogen (O'Neil, 1998; Trzeciak, 1995). Since nitrogen cycling in the environment is a very complex process and its intensity depends on many factors (e.g., oxygenation, temperature, season, primary production, etc.), as well as the amount of nutrient input from point sources, diffuse sources and deposition from the atmosphere (Boynton et al., 1995; Fisher et al., 1988), it is impossible to calculate the nitrogen load that will enter the water column from the sediment during foundation placement activities.

It was assumed that all of the sediment that would be removed from the foundation sites during bottom preparation would be left in the farm area. Similarly, in the case of the use of a different type of foundation (planned to be implemented - monopal or jacket, other types of foundations may involve only one foundation for supporting infrastructure), where the area of disturbance of the bottom and the sediments on it is much smaller, the impact will be at a level many times lower.

At the same time, the processes of stirring up bottom sediments can slightly improve sediment quality (increasing sediment oxygenation and reducing the amount of pollutants and nitrogen compounds in the sediment due to their transition to the water tone). Better oxygenation of the sediment, on the other hand, can reduce (limit) the passage of phosphorus from the sediment, since this process occurs under anaerobic (reducing) conditions (Alloway and Ayres, 1999).

Substances released from the sediment will pass into the water body, however, during a period of about 1 year after the cessation of construction activities, these substances will pass back into the sediment after reaching equilibrium.

The release of pollutants and nutrients from bottom sediments is a direct, negative impact during the construction phase that is regional in scope, short-term, reversible or irreversible, repeatable during the construction period, with an intensity ranging from low (areas P1 and P3) to medium or high (areas P2, P4 and P5).

The 2015 Report, which is the basis for the issuance of the current Environmental Decision, assessed the significance of this impact for the most far-reaching scenario (NIS 2015), as quoted below in Table 11, with the impacts for the variant approved in the Environmental Decision assessed as lower.

Table 11. Impact assessment involving the release of pollutants and nutrients from sediment into the water body (construction phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Seabed / bottom sediments	Large (areas P1 and P3)	Low (areas P1 and P3)	During the construction of the farm, there will be a release of pollutants and nutrients from the sediment into the water body	Negligible (scale of exposure - regional, duration - short-term, intensity - low)	Small (magnitude of impact - insignificant, importance of the resource - high)
	Medium (areas P2, P4 and P5)	Medium (areas P2 and P4) or high (area P5)		Small (scale of exposure - regional, duration - short-term, intensity - medium to high)	Small (magnitude of impact - low, importance of the resource - medium)
Marine waters	Medium	Average		Small (scale of exposure - regional, duration - short-term, intensity - low to high)	Small (magnitude of impact - low, importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

In summary, the variant that is the subject of this Report will build about 70% fewer foundations than the furthest-reaching scenario - NIS 2015 - that forms the basis of the assessment in the 2015 Report, and twice as many as specified in the Environmental Decision, and the use of gravity foundations under the power plants has been ruled out, which is associated with a smaller area of disturbed sediment and, consequently, correspondingly fewer heavy metals, pollutants and nutrients released from it. It is therefore considered that the project will cause significantly lower impacts than both those assessed for the 2015 NIS and the variant approved in the Environmental Decision.

Thus, it should be considered that the nature of the impacts does not change, while their scope and intensity are significantly smaller than in the case of the variant approved by the Environmental Decision, and thus the proposed change in the parameters of implementation and operation of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.1.3. Changing the substrate composition of bottom sediments bottom sediments

A change in the substrate composition of bottom sediments can occur as a result of two types of work carried out during the construction phase of the farm:

- laying a protective layer against leaching around the base of the foundation;
- replacement of the subsoil at the site of the planned gravity foundation with a material with a higher bearing capacity.

Foundations used for OWF facilities, especially gravity and monopiles, are susceptible to leaching of bottom sediments in the immediate vicinity of their bases. Therefore, a so-called "leaching protection layer" is laid around them. For this purpose, rock ballast, stones and boulders are most often used, with which the base of the foundation is surrounded by a width of several to several meters (see Sections 3 and 4 of Volume II of the EIA). Environmentally neutral materials are used. Hydraulic stone, obtained from granite, dolomite, sandstone or basalt rock, is commonly used in marine hydraulic engineering. It is used, among other things, in the construction and upgrading of breakwaters, shorelines, banks and bottoms of water channels, strengthening of the bottom and slopes of river channels (as flood protection), rock erratics, foundations, as well as port facilities, marinas and ferries.

Currently, the developer assumes that such a layer can be used in any type of foundation that is being considered for use in the BIII OWF project. The most far-reaching scenario (NIS 2015), which formed the basis for conducting the assessment in the 2015 Report, envisioned the construction of a maximum of 200 gravity foundations, for which the change in substrate composition would occur over the largest area (50 m - the diameter of the foundation plus 10 m of leaching protection layer counting from the foundation periphery). A layer of stones and boulders can also be used to cover power cables if they are not buried to the proper depth. The decision on the use of the protective layer and its width can be made only at the stage of the construction project, after determining the field conditions at specific locations of the foundations. The variant currently planned for implementation involves the construction of only 60 foundations for turbines, and provides for the possibility of using gravity foundations only for associated infrastructure (1 unit), while for wind power plants the choice of foundations has been limited to monopile or jacket foundations.

The degree of change in sediment substrate composition at a given location will depend directly on the structure of the seabed (see Section 3 and Section 5 of Volume III of the EIA). Bottom sediments in the P1 and P3 areas (outcrops of glacial till with a variable sand and gravel cover, with numerous pebbles on the surface) will have a low susceptibility to changes in the sub-saturated composition due to poor sorting (presence of all fractions in the composition). The clays also provide a stable foundation for power plant construction. Areas P2 and P5 (silty-muddy sediments with a thick cover of sandy sediments), as well as area P4 (glacial till covered by a layer of sandy sediments with individual boulders on the surface), constitute a substrate that is not very stable, so it will be necessary to replace it before the foundations are laid. Sensitivity to changes in substrate composition was rated as low to medium. These areas are characterized by a high and very high degree of sorting, and the change in sediment substrate composition will be more noticeable here.

The appearance of coarse rock crumbs can contribute to the creation of new habitats for sessile benthic organisms. Therefore, the change in sediment substrate composition should be considered a positive impact.

Due to the lack of significant impacts, minimization measures are not required, while the selection of appropriate foundations at the stage of construction design can reduce the scale of impacts.

The change in sediment substrate composition is a direct, positive impact at the construction stage that is local in scope, long-term, irreversible, and repeatable during the construction period. The intensity of

the impact in the P1 and P3 areas was determined to be medium, and in the P2, P4 and P5 areas it was determined to be high.

The 2015 Report, which is the basis for the issuance of the current Environmental Decision, assessed the significance of this impact for the most far-reaching scenario (NIS 2015), as quoted below in Table 12, with the impacts for the variant approved in the Environmental Decision assessed as lower.

Table 12. Impact assessment involving changes in the substrate composition of bottom sediments (construction phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Seabed / bottom sediments	Large (areas P1 and P3)	Low	During the construction of the farm, there may be a change in the sub-fractional composition of the bottom sediments	Small (scale of exposure - local, duration - long-term, intensity - medium)	Small (magnitude of impact - low, importance of the resource - high)
	Medium (areas P2, P4 and P5)	Low (P2, P4) or medium (P5)		Moderate (scale of exposure - local, duration - long-term, intensity - high)	Small (magnitude of impact - moderate, importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

The variant that is the subject of this Report will build about 70% less foundation than envisioned for the farthest-reaching scenario - the NIS 2015 - that forms the basis of the assessment in the 2015 Report, and twice as much as specified in the Environmental Decision. In the currently proposed variant selected for implementation for wind turbines, the use of gravity foundations has been ruled out, while this type of foundation can be used for the construction of an internal offshore substation (1 unit). In the case of the latter foundation, the unit size of the occupied area is larger, but nevertheless, as the number changes from six to one, the total impact will decrease.

Accordingly, the change in the subfractional composition of bottom sediments will occur in a correspondingly smaller number of locations and over a correspondingly smaller area. It is therefore considered that the Project will cause significantly lower impacts from both the Project in the parameters constituting the 2015 NIS and the variant approved in the Environmental Decision.

Thus, it should be considered that both the nature of the impacts does not change and their scope and intensity are significantly smaller than in the case of the variant approved by the Environmental Decision, and thus the proposed change in the parameters of implementation and operation of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.1.4. Structural disorder bottom

Disturbance of the bottom structure can occur as a result of several types of construction work, in particular:

- laying a protective layer against leaching around the base of the foundation;

- replacement of the subsoil at the site of the planned gravity foundation with a material of greater bearing capacity and deposit the excavated material in the farm area;
- preparation of the bottom for other types of foundations or cables, if necessary;
- driving or drilling foundation piles.

The 2015 Report assessed impacts on the bottom structure for the gravity foundation option, which was analyzed at the time as the parameters comprising the most far-reaching scenario (NIS 2015).

If gravity foundations are used, the disturbance of the bottom structure will be related to the need for proper preparation of the subsoil before foundation. This construction requires a stable foundation, so it will be necessary to replace it with rock material with a higher bearing capacity. Typically, a layer of sediment about 2 - 3 meters thick is removed, while if the sediment beneath the bottom surface has too little bearing capacity, it may be necessary to remove the entire overburden up to the parent layer, on which foundation is possible. This is especially true for areas P5 and P2 located in the western part of the BIII OWF, where silty clay sediments are present in the deep structure. If the slope of the bottom is too steep, the ground should be leveled.

Thus, it can be assumed that for a 40 m diameter gravity foundation and the application of 15 m wide scour protection from the foundation perimeter, it will be necessary to remove a sediment layer of about 11,539.5^{m3} and replace it with rock ballast.

Currently, the proposed variant involves the use of a less invasive solution, i.e. monopal or jacket foundations for power plants, while gravity foundations will only be allowed for associated infrastructure, with the number of such foundations reduced from 6 to 1 unit.

If monopiles are used, disruption of the bottom structure will be caused by drilling or driving the foundation pile. Driving or drilling the pile causes vibrations that can liquefy the top layer of sandy sediments within a few meters of the pile. This effect can occur in areas P2 and P5, where there is a thick layer of sandy sediments or sands on silts and clays. The liquefaction process usually leaves no molds on the bottom (it brings the bottom surface into alignment) and stops when the vibration ends. Monopiles can be used on gravel, sand or clay substrate provided there is a stable bedding layer. The monopile technique is less suitable under conditions of high density of boulders and rocks, and where silty-muddy sediments predominate in the deep structure (Hammar, et al., 2008). With regard to the aforementioned limitations, areas P1, P3, P4 (due to the presence of stonework) and area P5 (the presence of a thicker clay layer) may show low suitability for this type of foundation. However, this must be confirmed by geotechnical testing, which will take place only at the stage of the construction project.

The foundation of tripod and jacket foundations involves digging or drilling three to four piles up to 70 meters long (depending on terrain conditions) into the bottom, on which the foundation structure will then be set. Pile driving causes vibrations that can liquefy the sediment, similar to monopiles. The liquefaction process can occur where sandy or silty-clay deposits are present (areas P2, P5). The liquefaction process stops when the vibration stops. Due to piling, jackets are not the best alternative in areas of dense rock cover, so areas P1, P3 and P4 will have low suitability for this type of foundation. However, this must be confirmed by geotechnical testing.

Disturbance of the bottom structure will also occur during the laying of power cables. It is assumed that the breach will occur in sections with a total length of up to 200 km, its depth will be up to 1.5 m, and its width - about 1.5 m.

The degree of disturbance to the bottom structure in a given location will depend directly on its structure.

The seabed in areas P1 and P3 (outcrops of glacial till with a variable sand and gravel cover, with numerous pebbles on the surface) will have a high sensitivity to the analyzed impact, because when the clay structure is disturbed (drilling, digging), the processes to restore it to its original state are long.

The bottom in areas P2 and P5 (silty-muddy sediments with a thick cover of sandy sediments), as well as area P4 (glacial till covered by a layer of sandy sediments with individual boulders on the surface) will be easily disturbed in structure, but the process of restoration is much shorter than in areas P1 and P3. Sensitivity was rated medium in this case.

Due to the lack of significant impacts, minimization measures are not required, while the selection of appropriate foundations at the stage of construction design can reduce the scale of impact.

Disturbance of the bottom structure is a direct, negative impact of local extent at the construction stage, long-term, irreversible, repeatable during the construction period. The intensity of the impact in the P1 and P3 areas was determined to be medium, and in the P2, P4 and P5 areas it was determined to be high.

As mentioned above, the 2015 Report, the basis for the issuance of the current Environmental Decision, assessed the significance of this impact for the most far-reaching scenario, as quoted below in Table 13, with the impacts for the variant approved in the Environmental Decision assessed as less.

Table 13. Impact assessment involving disturbance of bottom structure (construction phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Seabed / bottom sediments	Large (areas P1 and P3)	High	During the construction of the farm, the bottom structure will be breached	Moderate (scale of exposure - local, duration - long-term, intensity - high)	Moderate (magnitude of impact - moderate, importance of the resource - high)
	Medium (areas P2, P4 and P5)	Average		Small (scale of exposure - local, duration - long-term, intensity - high)	Small (magnitude of impact - moderate, importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

In the variant that is the subject of this Report, about 70% fewer foundations will be built than envisioned for the furthest-reaching scenario - NIS 2015 - that forms the basis of the assessment in the 2015 Report, and twice as many as specified in the Environmental Decision, and the use of gravity foundations under the power plants has been ruled out, so violations of the bottom structure will occur over a significantly smaller area. It is therefore considered that the Project will cause lesser impacts from both the Project in the parameters constituting the 2015 NIS and the variant approved in the Environmental Decision.

Thus, it should be considered that both the nature of the impacts does not change and their scope and intensity are smaller than in the case of the variant approved by the Environmental Decision, and thus the proposed change in the parameters of implementation and operation of the Project does not affect

the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.1.5. Change in morphology fundus

A change in the morphology (shape) of the bottom can occur as a result of several types of construction work, in particular:

- laying a protective layer against leaching around the base of the foundation;
- replacement of the subsoil at the site of the planned gravity foundation with a material of greater bearing capacity and deposit the excavated material in the farm area;
- preparation of the bottom for other types of foundations or cables, if necessary;
- driving or drilling foundation piles.

The 2015 Report assessed impacts on bottom structure for the gravity foundation option, which was analyzed at the time as the most far-reaching scenario (NIS 2015).

The use of gravity foundations involves a change in the shape of the bottom as a result of the work being carried out. Material that is excavated as a result of foundation work must be temporarily deposited on the seabed immediately adjacent to the location where the work is being carried out, and can then be used as a protective layer, ballast (Peire et al., 2009) or to backfill internal infrastructure cables of the OWF.

Currently, the proposed variant assumes less bottom-interfering solutions, i.e. monopal or jacket foundations for power plants, while gravity foundations will only be allowed for associated infrastructure (1 unit).

If monopiles are used, the change in bottom morphology will be primarily related to the placement of a leaching protection layer around the pile.

The foundation of jacket foundations is associated with relatively minor changes in the morphology of the bottom, compared to gravity or monopile foundations, because they involve a much less frequent application of a protective layer against leaching. On soft ground (silt, clay) it is possible to use additional mats to increase the bearing capacity of the soil near the piles (so-called mudmats).

A slight change in the shape of the bottom can also occur during the laying of power cables. The bottom sediments disturbed during these works may be diluted. This will create a cavity along the cable or / and it may be temporarily exposed.

The degree of change in the morphology of the bottom in a given location will depend directly on its structure. Compact formations such as glacial till are not very susceptible to a change in morphology, however, if the morphology changes, it takes a long time to return to its original state (P1, P3). Vulnerability of areas P2, P4, P5 is high, but on the other hand, they return to their initial state just as easily due to bottom processes (movement of sediments by currents and wave action).

Due to the lack of significant impacts, minimization measures are not required, while the selection of appropriate foundations at the stage of construction design can reduce the scale of impacts.

Changing bottom morphology is a direct and negative impact during the construction phase, with a local scope. In P1 and P3 areas, it will be irreversible, long-term and high-intensity, while in P2, P4 and P5 areas it was considered a reversible, medium-term and medium-intensity impact.

The 2015 Report, the basis for the issuance of the current Environmental Decision, assessed the significance of this impact for the most far-reaching scenario, the 2015 NIS, as quoted below in Table 14, with the impacts for the variant approved by the Environmental Decision assessed as lower.

Table 14. Impact assessment involving alteration of bottom morphology (construction phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Seabed / bottom sediments	Large (areas P1 and P3)	Low (areas P1 and P3)	During the construction of the farm, the morphology of the bottom will change	Moderate (scale of exposure - local, duration - long-term, intensity - high)	Moderate (magnitude of impact - moderate, importance of the resource - high)
	Medium (areas P2, P4 and P5)	Medium (areas P2 and P4) or high (area P5)		Small (scale of exposure - local, duration - medium-term, intensity - high)	Small (magnitude of impact - low, importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

In the variant that is the subject of this Report, about 70% fewer foundations will be built than envisioned for the furthest-reaching scenario - NIS 2015 - that forms the basis of the assessment in the 2015 Report, and twice as many as specified in the Environmental Decision, and the use of gravity foundations under the power plants has been excluded, so violations of bottom morphology will occur over a correspondingly smaller area. It is therefore considered that the Project will cause lesser impacts from both the Project in the parameters constituting the 2015 NIS and the variant approved in the Environmental Decision.

Thus, it should be considered that both the nature of the impacts does not change and their scope and intensity are smaller than in the case of the variant approved by the Environmental Decision, and thus the proposed change in the parameters of implementation and operation of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.1.6. Settlement of the ground

A foundation planted on the seabed will cause soil compaction, that is, compaction due to the reduction of free spaces between sediment grains. As a result, the foundation will settle.

This process will occur mainly in the case of heavy gravity foundations, which weigh up to about 7,000 tons (see Section 2 of Volume II of the EIA). Such a solution was analyzed as an alternative (which is also the most far-reaching scenario - NIS 2015) in the 2015 Report. The impact of the currently proposed solution of using other types of foundations for power plants (monopile or jacket type) and allowing gravity foundations only for associated infrastructure, due to their lighter weight, will be much smaller.

The degree of soil compaction in a given location will depend directly on the construction of the bottom. The impact will be more noticeable in areas of silty clay sediments (P2, P5) and loosely packed sandy-gravel sediments (P4). Areas P1 and P3 are subject to lesser levels of ground subsidence. This is because

clays have a low sensitivity to sediment compaction under pressure, so they make a stable foundation for building foundations.

Due to the lack of significant impacts, minimization measures are not required, while the selection of appropriate foundations (abandonment of gravity foundations) will reduce the scale of impact.

Land subsidence is a direct, negative, long-term, irreversible, local impact. In P1 and P3 areas it will be characterized by low intensity, in P2 and P5 areas by high intensity.

The 2015 Report, the basis for the issuance of the current Environmental Decision, assessed the significance of this impact for the most far-reaching scenario, as quoted below in Table 15, with the impacts for the variant approved in the Environmental Decision assessed as lower.

Table 15. Impact assessment involving ground settlement (construction phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Seabed / bottom sediments	Large (areas P1 and P3)	Low	During the construction of the farm there will be a process of subsidence of the bottom	Negligible (scale of exposure - local, duration - long-term, intensity - low)	Small (magnitude of impact - insignificant, importance of the resource - high)
	Medium (areas P2, P4 and P5)	Medium (areas P2 and P4) or high (area P5)		Moderate (scale of exposure - local, duration - long-term, intensity - high)	Small (magnitude of impact - moderate, importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

In the variant that is the subject of this Report, about 70% fewer foundations will be built than envisaged in the case of the furthest-reaching scenario that forms the basis of the assessment in the 2015 Report - NIS 2015, and twice as many as specified in the Environmental Decision, and the use of gravity foundations under the power plants has been excluded, so the phenomenon of land subsidence will occur in a correspondingly smaller number of locations and over a correspondingly smaller area. It is therefore considered that the Project will cause significantly lower impacts from both the Project in the parameters constituting the 2015 NIS and the variant approved in the Environmental Decision.

Thus, it should be considered that both the nature of the impacts does not change and their scope and intensity are significantly smaller than in the case of the variant approved by the Environmental Decision, and thus the proposed change in the parameters of implementation and operation of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.1.7. Use of sand as ballast for foundations gravity

Gravel sand deposits identified in the farm area could be used as ballast to fill gravity foundations, if such would be used in the project (possibly to produce concrete gravity foundations). During construction, the demand for raw materials increases, in order to reduce construction costs, such

solutions are used. However, this would require obtaining a license in accordance with the Law of June 9, 2011. Geological and Mining Law (ie: Journal of Laws 2021 No. 1420) and the Regulation of the Minister of the Environment of July 1, 2015 on geological documentation of a mineral deposit, excluding hydrocarbon deposits (Journal of Laws No. 987) and the performance of a separate EIA to determine the possible negative effects of the extraction of these raw materials.

The extraction of raw materials for the construction of gravity foundations is beneficial to the investor, but at the same time the raw material resource of the South Baltic will be reduced irreversibly. This would be a direct, positive or negative impact on these raw materials, local in scope, long-term, irreversible, repeatable during the construction period, with very high intensity.

The impact does not apply to hydrocarbon deposits. Minimization measures are not required.

The 2015 Report, which is the basis for the issuance of the current Environmental Decision, assessed the significance of this impact for the most far-reaching scenario (NIS 2015), as quoted below in Table 16, with the impacts for the variant approved in the Environmental Decision assessed as lower.

Table 16. Impact assessment involving the use of gravel sands from exposed deposits for gravity foundations (construction phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Gravelly sand deposits	Medium	High	Four small potential gravel sand deposit fields have been identified within the boundaries of the future BSIII OWF and its buffer	Moderate (scale of exposure - local, duration - long-term, intensity - very high)	Small (magnitude of impact - moderate, importance of the resource - medium)

In the variant that is the subject of this Report, about 70% fewer foundations will be built than envisaged for the furthest-reaching scenario that forms the basis of the assessment in the 2015 Report - NIS 2015, and twice as many as specified in the Environmental Decision, and the use of gravity foundations under power plants has been ruled out (only such a foundation under a substation has been allowed), so the potential demand for raw materials for foundation construction will be significantly lower, or not at all. Thus, it is considered that the Project will cause significantly lower impacts from both the Project in the parameters constituting the 2015 NIS and the variant approved in the Environmental Decision.

Thus, it should be considered that both the nature of the impacts does not change and their scope and intensity are much smaller than in the case of the variant approved by the Environmental Decision (or the impact will not occur at all), and thus the proposed change in the parameters of implementation and operation of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.1.8. Wiping out, shoveling out or backfilling accumulations of raw materials minerals

During the construction of the BIII offshore wind farm, work will be carried out that will disturb the structure and morphology of the seabed.

Potential deposits of crumb raw materials may be affected by the uplift of bottom sediments caused by construction activities. This can lead to leaching or depletion of mineral accumulations during

foundation preparation or covering them with an additional layer of sediment from the excavated material, preventing their extraction, by increasing the thickness of the overburden above the deposit.

There may also be a disturbance of sediment movement in the bottom zone. The successively rising foundations of the power plant will be an obstacle to the displaced sediment. As a result, this can lead to the accumulation and/or leaching of sediment, resulting in the leaching of bed deposits or their backfilling.

The stored excavated material can bury potential deposits of crumb raw materials.

Thus, these will be direct negative impacts on crumbling raw materials at the construction stage, local in scope, short-term, reversible, repeatable during the construction period, with high intensity.

This impact does not apply to hydrocarbon deposits. Minimization measures are not required.

The 2015 Report, which is the basis for the issuance of the current Environmental Decision, assessed the significance of this impact for the most far-reaching scenario (NIS 2015), as quoted below in Table 16, with the impacts for the variant approved in the Environmental Decision assessed as lower.

Table 17. Impact assessment of leaching, selection or backfilling of mineral accumulations (construction phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Gravelly sand deposits	Medium	High	Four small potential gravel sand deposit fields have been identified within the boundaries of the future BSIII OWF and its Buffer	Small (scale of exposure - local, duration - short-term, intensity - very high)	Small (magnitude of impact - low, importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

The variant that is the subject of this Report will build about 70% fewer foundations than envisioned for the NIS 2015 furthest-reaching scenario that forms the basis of the assessment in the 2015 Report, and twice as many as specified in the Environmental Decision, and the use of gravity foundations under the power plants has been ruled out, so that leaching, excavation or backfilling of mineral accumulations will occur over a correspondingly smaller area. It is therefore considered that the Project will cause lesser impacts from both the Project in the parameters constituting the 2015 NIS and the variant approved in the Environmental Decision.

Thus, it should be considered that both the nature of the impacts does not change and their scope and intensity are smaller than in the case of the variant approved by the decision, and thus the proposed change in the parameters of implementation and operation of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.1.9. Occupation of the seabed area seabed

Subsequent foundations, embedded in the seabed during construction, will occupy an increasing area until their target number is reached.

Occupied by the gravity foundation, analyzed as an alternative option and also the most far-reaching scenario (NIS 2015) in the 2015 Report, the bottom area is about 3848.5^{m2} (including the 40 m diameter of the foundation and additionally the assumed maximum width of the leaching protection layer, i.e. 15 m from the edge of the foundation, giving a total diameter of 70 m). For 208 foundations (200 power plants and 8 foundations under supporting infrastructure), this gives a total of about 800,384^{m2} (0.8 ^{km2}).

Currently, other solutions (monopile and jacket foundations) are provided for wind power plants, while gravity foundations are allowed only for supporting infrastructure (1 unit).

Thus, in the case of the currently proposed solutions for the power plant, the area will be significantly smaller. With a monopile, the area for one foundation is about 1,963^{m2} (monopile diameter 10 m, width of protective layer 20 m), with a jacket for one foundation is 1,493^{m2} (pile diameter 1.8 m, width of protective layer around each of 4 piles - 10 m), and with a tripod for one foundation - 1,193^{m2} (pile diameter 2.5 m, width of protective layer around each of 3 piles - 10 m).

With a maximum of 200 kilometers of cable and 1.5 meters of cable trench width, the area occupied by the cable will be 300,000^{m2} (0.3 ^{km2}).

As can be seen from the above calculations, the area of occupied seabed for the set of parameters of the Project constituting the furthest-reaching scenario in the 2015 Report - NIS 2015, will be only about 1.1 ^{km2}, or about 0.94% of the area of the farm specified in the PSZW (about 117 ^{km2}) and about 1.17% of the area actually possible to develop with power plants (about 94 ^{km2}). In both the variant approved by the Environmental Decision and the variant that is the subject of this Report, this area will be even smaller.

Minimization measures are not required.

Seabed occupation is a direct, negative, long-term, reversible, localized impact during the construction phase. The intensity of impact when gravity foundations were used was assessed as high, and when other foundations were used as medium.

As mentioned above, the 2015 Report, the basis for the issuance of the current Environmental Decision, assessed the significance of this impact for the most far-reaching scenario, as quoted below in Table 17, with the impacts for the variant approved in the Environmental Decision assessed as less.

Table 18. Impact assessment involving seabed occupation (construction phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Seabed / bottom sediments	Large (areas P1 and P3)	Low	The seabed will be occupied during the construction of the farm	Moderate (scale of exposure - local, duration - Long-term, intensity - high)	Moderate (magnitude of impact - moderate, importance of the resource - high)
	Medium (areas P2, P4 and P5)	Low		Moderate (scale of exposure - local, duration -	Small (magnitude of impact -

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
				long-term, intensity - high)	moderate, importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

In the currently proposed variant selected for implementation, there has been a reduction in the number of wind power plants planned to be built to 60 units (by 70% compared to the furthest-reaching scenario - NIS 2015 - that formed the basis of the assessment in the 2015 Report, and by half compared to the variant approved by the Environmental Decision) and the types of foundations on which they can be placed to monopile foundations and jacket foundations. Clarifying the types of foundations and reducing their number has a direct bearing on the scale of seabed occupation in connection with the Project, since the use of gravity foundations causing the greatest interference with the seabed and its occupation for a single foundation among all the types of foundations considered so far has been ruled out for wind power plants.

In the variant selected for implementation, the largest occupation of the bottom for a single wind turbine foundation will be for the installation of a 10-meter-diameter monopile foundation and will amount to 78.5^{m2}. Since the type of foundation for the internal offshore substation was not specified, it was assumed that the largest bottom occupation for it would occur in connection with the installation of a gravity foundation with a base diameter of 50 m and would amount to 1,963.5^{m2}. The maximum seabed occupation for all foundations of the BIII offshore wind farm in the variant selected for implementation, i.e. 60 monopile foundations and 1 gravity foundation, will amount to 6,673.5^{m2}, a reduction of about 99% from the original preferred option. Including scour protection layers with an estimated width counted from the perimeter of each foundation of 25 m for a monopile foundation and 10 m for a gravity foundation, the bottom occupation in this variant would be 173,492.5^{m2}, about 77% less than in the original preferred variant.

The above-described reduction in the maximum anticipated area of the seabed occupied by the implementation of the Project in the variant selected for implementation will result in a significant reduction in the area where seabed interference (sediment structure) will occur, as well as the destruction and permanent transformation of natural benthic habitats. Thus, the negative impacts of OWF BIII on the benthic habitats and benthic communities found in its area will be reduced.

With the reduction in the area of new hard substrate introduced into the environment due to the Project, the "artificial reef" phenomenon will be reduced. Instead, it should be emphasized that the environmental benefits of reducing interference with natural bottom habitats far outweigh any positive effects of the above-mentioned phenomenon.

Thus, it should be considered that both the nature of the impacts does not change and their scope and intensity are smaller than in the case of the variant approved by the Decision, and thus the proposed change in the parameters of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.1.10. Obstruction of access to mineral accumulations minerals

Installing foundations on the bottom will occupy the surface and prevent access to potential accumulations of crumb raw materials. The impact of foundations will depend on their type.

At this stage, it is difficult to determine the target number of wind turbines that may be built on the surface of the designated potential crumb accumulation fields in the BIII OWF field (see Section 4 of Volume III of the EIA). For the purposes of the 2015 Report, the following assumptions were made (for the set of parameters analyzed there that represent the most far-reaching scenario - NIS 2015):

- the occupation of the bottom area (including the protective layer) by the gravity foundation on a unit scale is about 3,848.5^{m2} (0.004 ^{km2});
- uniform distribution of foundations over the buildable area;
- the areas of designated potential fields of accumulation of crumb raw materials in the BIII OWF field will be used (see Section 4 of Volume III of the EIA);
- field No. 1 can include a maximum of 9 gravity foundations; Field No. 2 (total) - a maximum of 66 foundations; Field No. 3 - a maximum of 32 foundations; Field No. 4 - a maximum of 11 foundations; Field No. 5 - a maximum of 35 foundations;
- the area of the field occupied by foundations possible for foundation, expressed in %: P1 - 0.68%, P2 - 1.36%, P3 - 0.67%, P4 - 0.66%, P5 - 0.66%;
- the remaining undeveloped area of the field: P1 - about 5.05 ^{km2}, P2 - about 37.25 ^{km2}, P3 - about 18.22 ^{km2}, P4 - about 6.34 km2, P5 - about 20.31 ^{km2}.

In the currently proposed variant, gravity foundations are allowed only for associated infrastructure (1 piece), while for the power plant, solutions occupying a smaller area (monopile foundations or jacket types) will be used.

It is also important to note the positive aspect - temporary (i.e., until the farm is decommissioned) prevention of access to potential raw material deposits may result in treating them as a strategic resource for the future.

It will be at the stage of construction a direct, positive or negative impact on the deposits of crumb raw materials, with a local scale of impact, long-term, reversible (after the decommissioning of the farm facilities), with very high intensity.

On the other hand, analyzing the possibilities of exploration for hydrocarbon deposits, it should be noted that modern technology makes it possible to conduct reconnaissance even during the construction or operation of a wind farm. The technology requires the installation of special hydrophone lines (OBCs) on the bottom and the movement of a ship with a seismic wave source along and across the stretched hydrophone lines. However, this method makes it possible to eliminate towing behind the survey vessel of multi-kilometer sequences of survey equipment, and thus conduct surveys in a built-up body of water.

Exploration of hydrocarbon deposits in the area of a developed wind farm is much more expensive than those carried out by conventional methods. It is estimated that these are twice the cost of those using traditional methods.

While exploration can be carried out, resource exploitation in the OWF area can only take place to a limited extent. This is primarily related to the organization of ship traffic and its restriction in the case of development of the basin. The stream of vessels required to service a single mining platform would require the creation of separate corridors free of development. The risk of collision with the constructed wind farm infrastructure would also increase. It is possible to conduct limited extraction from a platform placed on the edge of a body of water developed by a wind farm, but using horizontal wells.

Occupation of the bottom surface is at the stage of construction is a direct negative impact on hydrocarbon deposits, local in scope, long-term, reversible, repeatable during the construction period (installation of subsequent foundations), with low intensity.

Minimization measures are not required.

An assessment of the significance of this impact for the furthest-reaching NIS 2015 scenario assessed in the 2015 Report is presented in Table 18, below.

Table 19. Impact assessment of impeding access to mineral accumulations (construction phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Gravelly sand deposits	Medium	High	Four small potential gravel sand deposit fields have been identified within the boundaries of the future BSIII OWF and its buffer	Moderate (scale of exposure - local, duration - long-term, intensity - very high)	Small (magnitude of impact - moderate, importance of the resource - medium)
Hydrocarbon deposits	Small	Average	Two hydrocarbon exploration and appraisal licenses encroach slightly on the farm area	Negligible (scale of exposure - local, duration - long-term, intensity - low)	Negligible (magnitude of impact - insignificant, importance of the resource - low)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

In the variant that is the subject of this Report, about 70% fewer foundations will be built than envisioned for the furthest-reaching scenario that forms the basis of the assessment in the 2015 Report - NIS 2015, and twice as many as specified in the Environmental Decision, and the use of gravity foundations under the power plants has been excluded, so the area of this impact will be significantly reduced. It is therefore considered that the Project will cause lesser impacts from both the Project in the parameters constituting the 2015 NIS and the variant approved in the Environmental Decision.

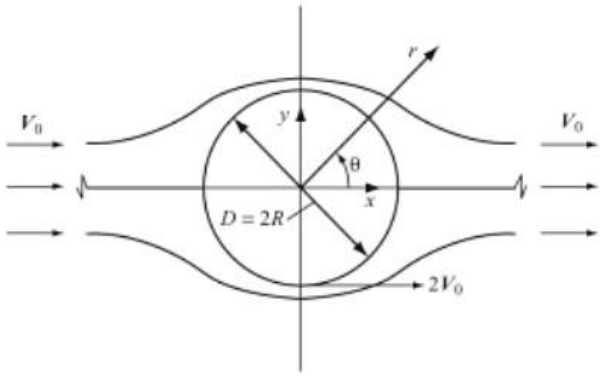
Thus, it should be considered that both the nature of the impacts does not change and their scope and intensity are smaller than in the case of the variant approved by the Environmental Decision, and thus the proposed change in the parameters of implementation and operation of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.1.11. Changes in the regime of currents seas

During the construction phase, more foundations for the power plant and other farm facilities will be located on the seabed and in the seabed. The ocean currents in the water's depths put a strain on OWF structures through hydrodynamic thrust. According to field measurements carried out by the Maritime Institute in Gdansk in the southern Baltic Sea (see Section 2 of Volume III of the EIA), they generally show similar intensity throughout the depth, i.e. have a similar distribution of velocities and flow directions in the vertical profile.

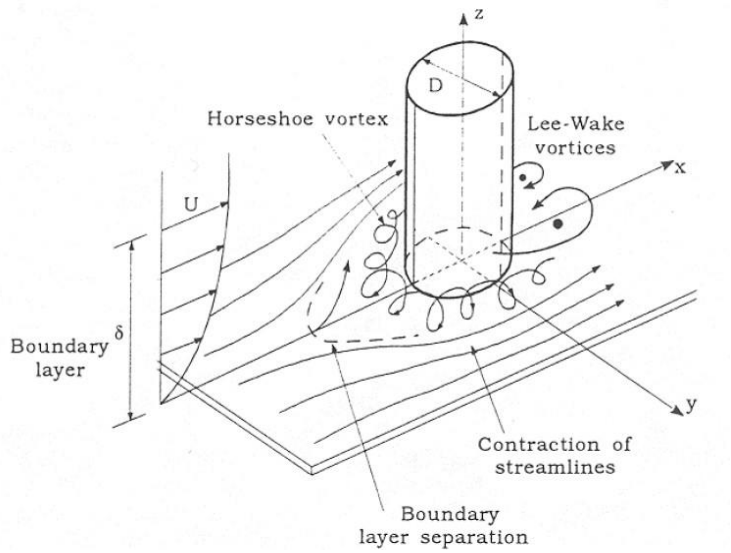
The impact of wind turbines on hydrological conditions manifests itself primarily in the modification of the flow field of marine currents. These currents, encountering an obstacle in the form of a support structure, flow around it. Then in the immediate vicinity of the structure there is a change in the velocity and direction of flow and water pressure. This results in a local increase in water velocity due to the narrowing of the flow stream and the formation of turbulence around the structure. The phenomenon of circumnavigation of a circular obstacle for potential flow is shown schematically in the figure below.

Figure 2. Surrounding by currents an obstacle with a circular cross-section (illustrative drawing)



Particularly important, and difficult to predict, is the formation of vortices around the structure - vortices can form both on the downstream side and directly in front of the obstacle (Figure 3).

Figure 3. Disturbance of the flow field around a vertical cylindrical structure exposed to the sea current (Hughes S.A., 2001)



The range of influence of the substructure on the flow of water in the seabed is equal to only a few diameters of the structure. In contrast, the distances between individual power plants are on the order of several hundred meters. This means that no overlap is expected between these impacts.

There are several factors that can affect the way the water flow field is modified due to the installation of wind turbines, such as:

- the number of wind turbines, the distance between them and how they are deployed;
- the dimensions and shape of the individual towers;
- type and dimensions of foundations;

- flow field characteristics (velocities, dominant directions, etc.);
- bathymetry with special attention to surface gradients and natural obstacles.

The assessment of the wind farm's impact of inducing changes in the regime of sea currents was based on the analyses contained in the hydrographic modeling report performed for the Central Baltic offshore wind farm III (SMDI, 2015).

The aforementioned hydrographic report modeled the changes in the regime of sea currents that will occur after the construction of the BSIII OWF. The analysis was performed for all project alternatives considered.

The analysis was performed for NIS 2015, for the months of January and July, for 5 control points located inside and outside the farm area. Once the farm is built, there will be a minimal reduction in the speed of the flow of ocean currents inside the farm. These will be velocity changes of up to about 0.5 cm/s in July and up to 1 cm/s in January. The average flow velocities recorded (see Section 2 of Volume II of the EIA) ranged from 8.44 to 17.73 cm/sec. The reduction in the speed of currents inside the wind farm will be offset by a slight increase in their speed outside the farm. The sensitivity of marine waters in the area of the farm was assessed as very low (negligible). The impact during the construction phase will therefore be even smaller, depending on how many foundations are installed at any given time.

Due to the lack of significant impacts, minimization measures are not required, while the selection of appropriate foundations at the stage of construction design can reduce the scale of impacts.

Changes in the regime of sea currents are direct, negative impacts of local scope, short-term (during the construction phase), irreversible, repeatable during the construction period, with low intensity.

An assessment of the significance of this impact for the furthest-reaching scenario assessed in the 2015 Report (NIS 2015), is presented in Table 19, below.

Table 20. Impact assessment involving change of sea current regime (construction phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Marine waters	Medium	Very low (negligible)	The foundation of the wind farm will affect the regime of sea currents in the investment area	Negligible (scale of exposure - local, duration - short-term, intensity - low)	Negligible (magnitude of impact - insignificant, importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

The variant that is the subject of this Report will build about 70% fewer foundations than envisioned for the case underlying the assessment in the 2015 Report of the most far-reaching scenario, the 2015 NIS, and twice as many as specified in the Environmental Decision, and the use of gravity foundations under the power plants has been ruled out, thus reducing the potential impact on ocean currents proportionally. It is therefore considered that the Project will cause lesser impacts from both the Project in the parameters constituting the 2015 NIS and the variant approved in the Environmental Decision.

Thus, it should be considered that both the nature of the impacts does not change and their scope and intensity are smaller than in the case of the variant approved by the Environmental Decision, and thus the proposed change in the parameters of implementation and operation of the Project does not affect

the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.1.12. Wave attenuation wind

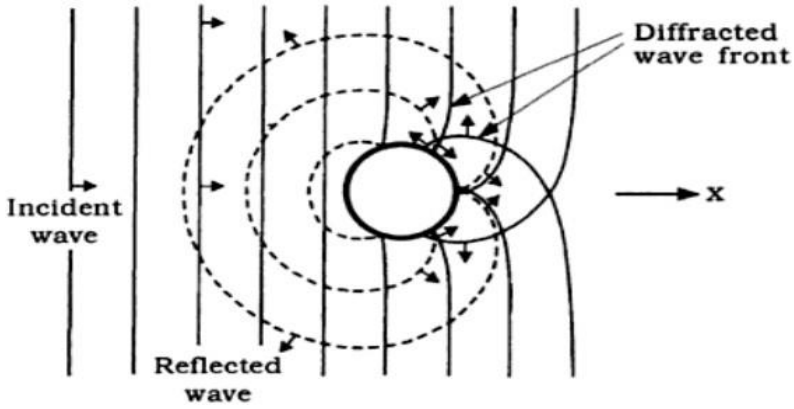
During the construction phase, more foundations for the power plant and other farm facilities will be located on the seabed and in the seabed. When waves hit the foundation of a wind turbine, some of their energy is reflected. This causes wave changes inside the wind farm and in its leeward zone.

Both wind waves on the free surface of the sea and ocean currents in the ocean's depths put stress on wind turbine towers through hydrodynamic thrust, with the impact of wind waves mainly confined to the water surface layer.

Since there is an interaction of hydraulic structures with hydrological phenomena occurring in the sea, the designs of individual wind turbines can also affect them to a certain, limited degree. This issue is primarily concerned with the impact on surface waves and currents.

If the diameters of wind power support structures are less than one-fifth the length of the waves propagating in their direction (Massel, 1992), we can consider such towers as streamlined structures. This means that they will not cause significant disturbance to the wave field. Otherwise, the waves approaching the structure will partly undergo reflection and partly symmetrical deflection of the wave ray behind the obstacle encountered, i.e. diffraction. This phenomenon is schematically shown in Figure 4, below.

Figure 4. Impact of a large diameter vertical cylindrical structure on the wave regime (Sumer B.M., Fredsøe j., 2005)



In the shadow area, i.e. immediately behind the obstacle encountered by the waves, there is no wave motion, but water turbulence can form there. In front of the structure, on the other hand, the reflected waves interferes with the incoming waves, resulting in standing waves. As a result, using rope theory for simplicity, the vertical orbital velocity doubles directly in front of the structure. If such waves are long enough to affect the bottom, they can, in cooperation with sea currents, contribute to sediment pick-up and consequently lead to erosion in the immediate vicinity of the structure's foundation.

The assessment of the wind farm's impact on marine waters, consisting of surface wave attenuation, was based on the environmental characteristics (see Section 2 of Volume III of the EIA) and on the analyses contained in the hydrographic modeling report performed for the Central Baltic III OWF (SMDI, 2015).

The aforementioned hydrographic report modeled the changes in wave patterns that will occur after construction of the BIII OWF. The analysis was performed for all project alternatives considered at the time.

The wave model in the area of the fully built-up farm indicates very small changes in wave height, on the order of a few centimeters, compared to the baseline. Meanwhile, the highest wave recorded during the survey by the Maritime Institute in Gdansk was 6.14 meters high, and the highest significant wave was 3.89 meters.

The average wave height (calculated as the average of all recorded average waves) for checkpoint 001 was 0.57 m, and 0.54 m for checkpoint 002.

The impact during the construction phase will therefore be even smaller, depending on how many foundations are installed at any given time.

No measures are expected to minimize this impact.

Wave attenuation during the construction stage of the farm is a direct, negative impact of local scope, short-term (during the construction stage), irreversible, repeatable during the construction period, low intensity.

An assessment of the significance of this impact for the furthest-reaching scenario assessed in the 2015 Report (NIS 2015), is presented in Table 20, below.

Table 21. Impact assessment involving surface wave attenuation (construction phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Marine waters	Medium	Very low (negligible)	The foundation of the wind farm will have an impact on the surface wave in the area of the project	Negligible (scale of exposure - local, duration - short-term, intensity - low)	Negligible (magnitude of impact - insignificant, importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

The variant that is the subject of this Report will build about 70% fewer foundations than envisioned for the furthest-reaching scenario that forms the basis of the assessment in the 2015 Report - NIS 2015, and twice as many as specified in the Environmental Decision, and the use of gravity foundations under the power plants has been ruled out, so its impact on wave action will be reduced proportionally. It is therefore considered that the Project will cause lesser impacts from both the Project in the parameters constituting the 2015 NIS and the variant approved in the Environmental Decision.

Thus, it should be considered that both the nature of the impacts does not change and their scope and intensity are smaller than in the case of the variant approved by the Environmental Decision, and thus the proposed change in the parameters of implementation and operation of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.1.13. An increase in the amount of suspended solids in the water

During the construction phase, more foundations for the power plant and other farm facilities will be located on the seabed and in the seabed. This will cause stirring of bottom sediments and temporary floating of suspended solids in the water depths.

The assessment of the wind farm's impact of reduced water transparency, caused by the floating of suspended solids in the water depths, was based on the environmental characteristics (see Sections 2,

3 and 5 of Volume III of the EIA) and analyses performed in 2015 for the Central Baltic III OWF (SMDI, 2015).

The seabed consists of fine sand and sand on clay substrate (see Sections 3 and 5 of Volume III of the EIA). It is a material prone to being picked up from the bottom and remaining suspended in the water's depths for some time. The possibility of this occurring in this area has been confirmed by modeling studies (SMDI, 2015). In addition, engineering practice shows that the most sludge is mobilized during the placement of gravity foundations, i.e., those originally considered for the power plant in the area of the proposed OWF BIII farm (the most far-reaching scenario evaluated in the 2015 Report - NIS 2015). However, it should be added here that this phenomenon is short-lived and locally limited. However, an increase in the concentration of suspended solids in the seabed may have a negative impact on the benthos, fish and marine mammals in the range.

In the aforementioned hydrographic report, the suspended solids uplift that will occur during the construction of OWF BIII was modeled. The analysis was performed for all project alternatives considered at the time. The average suspended solids concentration calculated by the model (SMDI, 2015a) is a maximum of 20 mg/l within the farm area and 10 mg/l outside the farm area, but will only average about 8 mg/l over most of the analyzed area. The average content of suspended solids in the near-surface and bottom layers in the BIII OWF area varies from about 1 mg/l to about 6 mg/l, depending on the time of year (increases occur in spring). It is estimated that suspended solids above 2 mg/L will not persist for more than approx. 40 h after agitation (IMG Consortium and MEWO et al., 2017; SMDI, 2015a).

There is no need for minimization measures.

The increase in suspended solids in water during the construction stage of the farm is a direct negative impact of local extent, medium-term (during the construction stage), reversible, repeatable during the construction period, with high intensity.

Assess the significance of this impact for the furthest-reaching scenario assessed in the 2015 Report (NIS 2015), Table 21 below.

Table 22. Impact assessment involving increase in suspended solids in water (construction phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Marine waters	Medium	Very low (negligible)	Construction of wind farm foundations will cause water turbidity in the project area	Small (scale of exposure - local, duration - short-term, intensity - very high)	Small (magnitude of impact - low, importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

The variant that is the subject of this Report will build about 70% fewer foundations than envisioned for the furthest-reaching scenario that forms the basis of the assessment in the 2015 Report - the 2015 NIS - and twice as many as specified in the Environmental Decision, and the use of gravity foundations under the power plants has been ruled out, so the level of potential water turbidity will decrease proportionally. It is therefore considered that the Project will cause lesser impacts from both the Project in the parameters constituting the 2015 NIS and the variant approved in the Environmental Decision.

Thus, it should be considered that both the nature of the impacts does not change and their scope and intensity are smaller than in the case of the variant approved by the Environmental Decision, and thus the proposed change in the parameters of implementation and operation of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.1.14. Impacts cumulative

Assumptions for analyses of the cumulative impacts of the BIII OWF and other projects on abiotic elements of the environment are presented in Chapter 3.2. On the other hand, a broad description regarding this issue can be found in Section 13 of Volume II of the EIA.

The impact assessment conducted in the 2015 Report assumed two possible scenarios for wind farm development in the POM for cumulative impact analyses presented below:

Between 2019 and 2021, power plants with a total capacity of 900 MW will be built, including 600 MW in OWF BIII and 300 MW in OWF Baltica 3. Assuming that the average power plant will have a capacity of 6 MW, it was assumed that 150 of them would be built. Associated infrastructure (substations, etc.) will also be built. It was assumed that 158 foundations and about 158 km of internal cables would be installed on the seabed in this connection.

The scenario estimates that the level of cumulative impacts on abiotic environmental elements will be about 75% of the level analyzed in the 2015 report as an alternative, the NIS.

Between 2023 and 2026, power plants with a total capacity of 1,350 MW will be built, including 600 MW under OWF BIII and 750 MW under OWF Baltica 2. It was assumed that a total of 225 wind turbines would be built. Associated infrastructure will also be built. It was assumed that 232 foundations and about 232 km of internal cables would be installed on the seabed in this connection.

It was estimated that in the above scenario, the level of cumulative impacts on abiotic environmental elements will be only about 16.5% higher than the level analyzed in the 2015 report for the set of parameters of the Project constituting the 2015 NIS.

Potential cumulative impacts may arise from the dissipation of suspended solids due to the disturbance of the bottom sediment structure, thereby releasing a certain pool of pollutants and nutrients from the sediment into the water body, turbidity of the water, and the possibility of covering raw material deposits with an additional layer of sediment. However, it was found that the level of this accumulation would be small or minimal (depending on the structure of the seabed).

Accumulation may also be associated with increased seabed occupation, however, the significance of this impact was assessed as low.

The variant that is the subject of this Report will build about 70% fewer power plants than envisaged in the case of the furthest-reaching scenario that forms the basis of the assessment in the 2015 Report - NIS 2015, and twice as many as specified in the Environmental Decision, and the use of gravity foundations under the power plants has been excluded, so that even in the case of cumulative impacts with those associated with the simultaneous construction of other power plants, the total impacts will be less than those assessed in the 2015 Report. It is therefore considered that the Project will contribute less to cumulative impacts, both from the Project in the parameters constituting the 2015 NIS and from the variant approved in the Environmental Decision.

Thus, it should be considered that both the nature of the impacts does not change and their scope and intensity are smaller than in the case of the variant approved by the Environmental Decision, and thus the proposed change in the parameters of implementation and operation of the Project does not affect

the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.2. Stage operation

During the operation of OWF BIII, works affecting the seabed and seawater will be carried out in its area, mainly maintenance works. In addition, the abiotic environment will be affected by foundation structures sited on the seabed.

A full description of the work during the operation stage is provided in Section 5 of Volume II of the Report.

The following impacts of OWF BIII on the abiotic environment at the stage of operation are expected:

- disruption of sediment structure;
- the release of pollutants and nutrients from the sediment into the water body;
- changing the substrate composition of sediments;
- disruption of the bottom structure;
- change in bottom morphology;
- ground settlement;
- seabed area occupation;
- leaching out or burying mineral accumulations;
- making access to mineral accumulations more difficult;
- contamination of the water tone and sediments with anti-corrosive agents;
- changing water and sediment temperatures;
- changing the regime of sea currents;
- wind wave attenuation;
- water turbidity.

Unplanned impacts may also occur during operation of the farm, which are described in detail in Section 12 of Volume II of the Report and in Chapter 11 of this section.

9.2.1. Disruption of the structure of sediments

During the operation of OWF BIII, works will be carried out to disturb the structure of the bottom sediments, such as replacing damaged sections of the power cable. There will also be an observation of the stirring of bottom sediment associated with the anchoring of ships during inspections, servicing and sudden emergency repairs (such as replacing a section of damaged cable). The anchoring process is short-lived, in a small area (spot), to a depth of about 3 meters. The amount of sediment that can be stirred up from the anchorage is small.

In addition, bottom sediments in the immediate vicinity of foundation structures will be washed away (scour effect). The average leaching value is 1.3 foundation diameters. Simulations conducted for typical North Sea conditions have shown this value to be much smaller, equal to 0.3 of the foundation diameter during periods of large waves (Nielsen, Hansen, 2007). As a result of the agitation of bottom sediments, some heavy metals, pollutants and nutrients will be released from them, and water turbidity may also occur. Aggradation of bottom sediments can also affect potential deposits of crumb raw materials. It can lead to leaching of raw materials or covering them with an additional layer of sediment, making it difficult to extract them, by increasing the thickness of the overburden above the deposit.

Given the hydrodynamic conditions in the Baltic Sea (see Section 3 of Volume III of the EIA), the depth of leaching is expected to be as low as or less than in the North Sea. In addition, at the stage of the construction project, foundation types suitable for the site conditions will be selected and, if necessary, a protective layer against leaching, which will significantly reduce this impact during the operational period.

Smaller disturbances to the sediment structure will occur in the P1 and P3 areas, and larger disturbances will occur in - P2, P4 and P5. The characteristics of these areas are presented in Sections 3 and 5 of Volume III of the Report.

The magnitude of the impacts will be reduced by a scour protection layer laid around the foundations, possibly along cable routes.

Due to the lack of significant impacts, minimization measures are not required, while the selection of appropriate foundations and leaching protection layers at the stage of construction design can reduce the scale of impacts.

Violation of the bottom sediment structure is a direct, negative impact at the operational stage that is local in scope, short-term, reversible, repeatable during the operational period, with intensity ranging from low (areas P1 and P3) or high (areas P2, P4 and P5).

The 2015 Report, which is the basis for the issuance of the current Environmental Decision, assessed the significance of this impact for the most far-reaching scenario (NIS 2015), as quoted below in Table 22, with the impacts for the variant approved in the Environmental Decision assessed as lower.

Table 23. Impact assessment involving disturbance of bottom sediment structure (operational phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Seabed / bottom sediments	Large (areas P1 and P3)	Low	During the operation of the farm, there will be minor disturbances to the structure of the bottom sediments	Negligible (scale of exposure - local, duration - short-term, intensity - low)	Small (magnitude of impact - insignificant, importance of the resource - high)
	Medium (areas P2, P4 and P5)	Medium (areas P2 and P4) or high (area P5)		Negligible (scale of exposure - local, duration - short-term, intensity - high)	Negligible (magnitude of impact - insignificant, importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

In the variant that is the subject of this Report, about 70% fewer foundations will be built than envisioned for the furthest-reaching scenario - NIS 2015 - that forms the basis of the assessment in the 2015 Report, and twice as many as specified in the Environmental Decision, and the use of gravity foundations under the power plants has been excluded, so the disturbance of the bottom sediment structure will occur over a correspondingly smaller area. It is therefore considered that the Project will cause lesser impacts from both the Project in the parameters constituting the 2015 NIS and the variant approved in the Environmental Decision.

Thus, it should be considered that both the nature of the impacts does not change and their scope and intensity are smaller than in the case of the variant approved by the Environmental Decision, and thus the proposed change in the parameters of implementation and operation of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.2.2. Release of pollutants and nutrients from the sludge into the water body water

During the operation of the BIII OWF, works will be carried out that cause agitation of bottom sediments, such as servicing of foundations, cables and anchoring of ships. They will favor the passage of pollutants and nutrients from the sediment into the water body.

Labile forms of metals, organic pollutants, i.e. polycyclic aromatic hydrocarbons (PAHs) and polychlorinated biphenyls (PCBs), biogenes (nitrogen and phosphorus) can pass into the water, as described in section 9.1.2 of this section. Higher contents of these substances may be found in silty clay sediments due to their greater absorption capacity (P2, P4, P5).

Since the bottom sediment in the area of the planned OWF is characterized by a low content of harmful substances (metals, PAHs, PCBs, TBT) and biogenic substances, thus the risk of their passage into the water body is low (it will cause a slight deterioration in water quality). The sensitivity of the bottom sediments to the above impacts was determined to be low or medium, depending on the type of substrate, and the sensitivity of the water was determined to be low.

The magnitude of the impacts will be reduced by a scour protection layer laid around the foundations, possibly along cable routes.

Due to the lack of significant impacts, minimization measures are not required, while the selection of appropriate foundations and leaching protection layers at the stage of construction design can reduce the scale of impacts.

The release of pollutants and nutrients from bottom sediments is a direct, negative impact at the operational stage that is local in scope, short-lived, reversible, repeatable during the operational period, and of low to medium intensity.

The 2015 Report, which is the basis for the issuance of the current Environmental Decision, assessed the significance of this impact for the most far-reaching scenario (NIS 2015), as quoted below in Table 23, with the impacts for the variant approved in the Environmental Decision assessed as lower.

Table 24. Impact assessment involving the release of pollutants and nutrients from sediment into the water body (operational phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Seabed / bottom sediments	Large (areas P1 and P3)	Low	During the operation of the farm, there will be spot stirring of the bottom sediments and release of the pollutants and nutrients contained therein into the water body	Negligible (scale of exposure - local, duration - short-term, intensity - low)	Small (magnitude of impact - insignificant, importance of the resource - high)
	Medium (areas P2, P4 and P5)	Medium (areas P2 and P4) or high (area P5)		Negligible (scale of exposure - local, duration - short term, intensity - medium)	Negligible (magnitude of impact - insignificant, importance of the resource - medium)
Marine waters	Medium	Low		Negligible (scale of exposure - local, duration - short term, intensity - medium)	Negligible (magnitude of impact - insignificant, importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

The variant that is the subject of this Report will construct about 70% fewer foundations than envisioned for the furthest-reaching scenario that forms the basis of the assessment in the 2015 Report - the NIS 2015, and twice as many as specified in the Environmental Decision, and excludes the use of gravity foundations under the power plants, which entails a smaller area of disturbed sediment and, consequently, correspondingly fewer heavy metals, pollutants and nutrients released from it. It is therefore considered that the Project will cause lesser impacts from both the Project in the parameters constituting the 2015 NIS and the variant approved in the Environmental Decision.

Thus, it should be considered that both the nature of the impacts does not change and their scope and intensity are smaller than in the case of the variant approved by the decision, and thus the proposed change in the parameters of implementation and operation of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.2.3. Change in the substrate composition of sludge

A change in the substrate composition of the bottom sediments may occur as a result of two types of work carried out during the construction stage of the farm, i.e. the laying of a leaching protection layer around the base of the foundation and the replacement of the substrate at the site of the planned gravity foundation with a material of greater bearing capacity. This is described in detail in section 9.1.3 of this section. The leaching protection layers introduced during construction will be applied throughout the life of the farm.

During maintenance work, it is possible to introduce additional hardened elements to prevent scouring, which can introduce changes (if rock erratics are used) to the sediment substrate composition. Rock surcharges and other forms of protection from scouring provide a so-called "artificial reef," a new habitat for benthic organisms and fish. The impact will be particularly significant in areas of loose sandy and silty-clay deposits (see Section 3 of Volume IV of the EIA).

No measures are expected to minimize this impact at the operation stage.

A change in the substrate composition of sediments is a direct, positive impact at the operational stage that is local in scope, long-term, irreversible, one-time. The intensity of the impact in the P1 and P3 areas was determined to be medium, and in the P2, P4 and P5 areas it was determined to be high.

The 2015 Report, which is the basis for the issuance of the current Environmental Decision, assessed the significance of this impact for the most far-reaching scenario (NIS 2015), as quoted below in Table 24, with the impacts for the variant approved in the Environmental Decision assessed as lower.

Table 25. Impact assessment involving changes in the substrate composition of bottom sediments (operational phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Seabed / bottom sediments	Large (areas P1 and P3)	Low	During the operation of the farm, leaching protection layers may be used to change the substrate composition of the sediments	Small (scale of exposure - local, duration - long-term, intensity - medium)	Small (magnitude of impact - low, importance of the resource - high)
	Medium (areas P2, P4 and P5)	Low (P2, P4) or medium (P5)		Moderate (scale of exposure - local, duration - long-term, intensity - high)	Small (magnitude of impact - moderate, importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

The variant that is the subject of this Report will build about 70% fewer foundations than envisioned for the furthest-reaching scenario that forms the basis of the assessment in the 2015 Report - NIS 2015, and twice as many as specified in the Environmental Decision, and the use of gravity foundations under the power plants has been ruled out, which also involves changing the substrate composition of sediments at a correspondingly smaller number of locations. It is therefore considered that the Project will cause lesser impacts from both the Project in the parameters constituting the 2015 NIS and the variant approved in the Environmental Decision.

Thus, it should be considered that both the nature of the impacts does not change and their scope and intensity are smaller than in the case of the variant approved by the Environmental Decision, and thus the proposed change in the parameters of implementation and operation of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.2.4. Structural disorder bottom

Disturbance of the bottom structure will occur during construction activities, as described in detail in section 9.1.4 of this section, but most of them are continuous changes (once the structure is disturbed, it will not return to its original state), so they will also remain during the operation stage (e.g., changes in the bottom associated with driving foundation piles into it). No additional work (drilling, hammering) is expected to take place during this time, so the scale of this impact will not increase. The evaluation of these changes therefore remains the same as for the construction phase.

No measures are expected to minimize this impact at the operation stage.

Disturbance of the bottom structure is a direct, negative impact at the stage of operation that is local in scope, one-time, long-term and irreversible. The intensity of the impact in the P1 and P3 areas was determined to be medium, and in the P2, P4 and P5 areas it was determined to be high.

Disturbance of the bottom structure is a direct, negative impact at the stage of operation that is local in scope, one-time, long-term and irreversible. Due to the absence of additional work, the intensity of impact in all areas was determined to be low.

The 2015 Report, which is the basis for the issuance of the current Environmental Decision, assessed the significance of this impact for the most far-reaching scenario (NIS 2015), as quoted below in Table 25, with the impacts for the variant approved in the Environmental Decision assessed as lower.

Table 26. Impact assessment involving disturbance of bottom structure (operational phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Seabed / bottom sediments	Large (areas P1 and P3)	Medium or high	During the construction of the farm, there will be a breach in the structure of the bottom, which will remain during the operation stage	Insignificant (scale of exposure - local, duration - long term, intensity - low)	Small (magnitude of impact - insignificant, importance of the resource - high)
	Medium (areas P2, P4 and P5)	Medium or high		Negligible (scale of exposure - local, duration - long-term, intensity - low)	Negligible (magnitude of impact - insignificant, importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

In the variant that is the subject of this Report, about 70% fewer foundations will be built than envisioned for the farthest-reaching scenario - NIS 2015 - that forms the basis of the assessment in the 2015 Report, and twice as many as specified in the Environmental Decision, and the use of gravity foundations under the power plants has been ruled out, so that the disturbance of the bottom structure will occur over a correspondingly smaller area. It is therefore considered that the Project will cause lesser impacts from both the Project in the parameters constituting the 2015 NIS and the variant approved in the Environmental Decision.

Thus, it should be considered that both the nature of the impacts does not change and their scope and intensity are smaller than in the case of the variant approved by the Environmental Decision, and thus the proposed change in the parameters of implementation and operation of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.2.5. Change in morphology fundus

The foundation of wind farm elements is associated with a change in the morphology (shape) of the bottom. Changes in bottom morphology will also occur during the operational stage. There may be changes in the geological processes of the seabed at wind turbine foundation sites. Locally, erosion may occur - foundation washout or sediment accumulation in the vicinity of foundations.

As a result of the geophysical surveys carried out in the BIII OWF area, which formed the basis for the 2015 Report, it was possible to identify areas of current bottom erosion. The bottom is washed out at least periodically in the southwestern and western parts of the P1 area, in the western part of P3, in the central part of P2 and in places in the valley (P4). It should be assumed that sediment flushing in the vicinity of OWF BIII infrastructure elements is possible at these sites. In the rest of the area, with regard to the dynamics of the aquatic environment (see Section 2 of Volume III of the EIA), minor, non-threatening to infrastructure elements, bottom scouring on the upstream side of bottom-founded facilities and the formation of sand drifts on the downstream side are expected. The emerging bottom forms should not be larger than those currently existing and moving. This phenomenon may be more intense in the P1 area (the area of sand waves), but the expected changes in the relief of the bottom will not be greater than the scale of the current and emerging forms on the bottom. There may be locally exposed or buried elements of the farm's internal cable infrastructure (cables connecting individual power plants within the field). A slight change in the shape of the bottom can also occur during maintenance work and, for example, replacement of power cables. The bottom sediments disturbed during these works may be diluted. This will create a cavity along the cable and/or it may be temporarily exposed.

No minimization measures are expected to be required at the operation stage.

The change in bottom morphology is a direct and negative, local in scope, irreversible and long-term impact at the operational stage. Its intensity in P1 and P3 areas will be low, in P4 medium and in P2 and P5 high.

The 2015 Report, which is the basis for the issuance of the current Environmental Decision, assessed the significance of this impact for the most far-reaching scenario (NIS 2015), as quoted below in Table 26, with the impacts for the variant approved in the Environmental Decision assessed as lower.

Table 27. Impact assessment involving change in bottom morphology (operational phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Seabed / bottom sediments	Large (areas P1 and P3)	Low	During the operation of the farm, changes in the morphology of the bottom will occur	Negligible (scale of exposure - local, duration - long-term, intensity - low)	Small (magnitude of impact - low, importance of the resource - high)
	Medium (areas P2, P4 and P5)	Medium (P2, P4) or high (P5)		Low or moderate (scale of exposure	Small (magnitude of

				- local, duration - long-term, intensity - medium or high)	impact - low or moderate, importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

The variant that is the subject of this Report will build about 70% fewer foundations than envisioned for the furthest-reaching scenario that forms the basis of the assessment in the 2015 Report - NIS 2015, and twice as many as specified in the Environmental Decision, and the use of gravity foundations under the power plants has been ruled out, which also involves changing the bottom morphology at a correspondingly smaller number of locations. It is therefore considered that the Project will cause lesser impacts from both the Project in the parameters constituting the 2015 NIS and the variant approved in the Environmental Decision.

Thus, it should be considered that both the nature of the impacts does not change and their scope and intensity are smaller than in the case of the variant approved by the Environmental Decision, and thus the proposed change in the parameters of implementation and operation of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.2.6. Settlement of the ground

The foundations of individual wind farm facilities, depending on the mass, can cause soil compaction, i.e. compaction due to a reduction in the number of free spaces between sediment grains, resulting in foundation settlement.

At the operational stage, the process of ground settlement under their weight will be slower than during construction, but still noticeable. It mainly concerns the use of heavy gravity foundations, assessed in the 2015 Report in the most far-reaching scenario (NIS 2015). In the current variant, the use of gravity foundations under the power plants was abandoned, and this solution was allowed only for the associated infrastructure (1 piece).

The impact will be more noticeable in areas of silty-clay sediments and loosely packed sandy-gravel deposits (P2, P4, P5). Areas P1 and P3 are also subject to ground subsidence, but to a lesser extent.

No measures are expected to minimize this impact at the operation stage.

Land subsidence is a direct, negative, long-term, irreversible, local impact at the operational stage. In P1 and P3 areas it will be characterized by low intensity, in P2 and P5 areas by high intensity. In the P4 area, the impact would have a high intensity only if gravity foundations are used, while it will be medium for the other types.

The 2015 Report, which is the basis for the issuance of the current Environmental Decision, assessed the significance of this impact for the most far-reaching scenario (NIS 2015), as quoted below in Table 27, with the impacts for the variant approved in the Environmental Decision assessed as lower.

Table 28. Impact assessment involving land subsidence (operational phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Seabed / bottom sediments	Large (areas P1 and P3)	Low	During the operation of the farm there will be a process of subsidence of the bottom	Negligible (scale of exposure - local, duration - long-term, intensity - low)	Small (magnitude of impact - insignificant, importance of the resource - high)
	Medium (areas P2, P4 and P5)	Medium (P2, P4) or high (P5)		Moderate (scale of exposure - local, duration - long-term, intensity - high)	Small (magnitude of impact - moderate, importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

The variant that is the subject of this Report will build about 70% fewer foundations than envisioned for the furthest-reaching scenario that forms the basis of the assessment in the 2015 Report - NIS 2015, and twice as many as specified in the Environmental Decision, and the use of gravity foundations under the power plants has been ruled out, which is also associated with the occurrence of less soil subsidence and in a correspondingly smaller number of locations. It is therefore considered that the Project will cause lesser impacts from both the Project in the parameters constituting the 2015 NIS and the variant approved in the Environmental Decision.

Thus, it should be considered that both the nature of the impacts does not change and their scope and intensity are smaller than in the case of the variant approved by the Environmental Decision, and thus the proposed change in the parameters of implementation and operation of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.2.7. Occupation of the seabed area seabed

The occupied bottom area of the gravity foundation is approximately 3848.5^{m2} (including the 40 m diameter of the foundation and, in addition, the assumed maximum width of the leaching protection layer, i.e. 15 m from the edge of the foundation, giving a total diameter of 70 m). The use of such foundations was analyzed in the 2015 Report as the most far-reaching scenario (NIS 2015). For the 208 foundations in the farthest-reaching scenario evaluated in the 2015 Report, this gives a total of about 800,384^{m2} (0.8 ^{km2}).

In the current variant, the use of gravity foundations under the power plants was abandoned, and this solution was allowed only for the associated infrastructure (1 piece).

In the case of the monopile, the area for one foundation is about 1,963^{m2} (monopile diameter 10 m, width of the protective layer 20 m), with the jacket for one foundation is 1,493^{m2} (pile diameter 1.8 m, width of the protective layer around each of 4 piles - 10 m), and with the tripod for one foundation - 1,193^{m2} (pile diameter 2.5 m, width of the protective layer around each of 3 piles - 10 m).

As can be seen from the above calculations, the area of occupied seabed if gravity foundations are used (as applied in the 2015 NIS) will be only about 0.8 ^{km2}, or about 0.68% of the area of the farm specified in the PSZW (about 117 ^{km2}) and about 0.85% of the area actually possible to develop with power plants (about 94 ^{km2}).

If other than gravity types of foundations are used, this area will be even smaller. For the variant selected for implementation (values given for 60 foundations), seabed occupation will amount to about 0.12 ^{km2} with monopiles, about 0.07 km2 with tripods, about 0.09 ^{km2} with jackets, respectively.

Seabed occupation is not expected to change during the operation of the farm. No measures are expected to minimize this impact at the operation stage.

Seabed occupation during the operation stage is a direct, negative, long-term, reversible, localized impact. The intensity of impact when gravity foundations were used was assessed as high, and when other foundations were used as low or medium.

The 2015 Report, which is the basis for the issuance of the current Environmental Decision, assessed the significance of this impact for the most far-reaching scenario (NIS 2015), as quoted below in Table 28, with the impacts for the variant approved in the Environmental Decision assessed as lower.

Table 29. Impact assessment involving seabed occupation (operational phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Seabed / bottom sediments	Large (areas P1 and P3)	Low	During the operation of the farm, seabed occupation will occur	Moderate (scale of exposure - local, duration - long-term, intensity - high)	Moderate (magnitude of impact - moderate, importance of the resource - high)
	Medium (areas P2, P4 and P5)			Moderate (scale of exposure - local, duration - long-term, intensity - high)	Small (magnitude of impact - moderate, importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

In the currently proposed variant selected for implementation, there has been a reduction in the number of wind turbines planned for construction to 60 units and the types of foundations on which they can be placed to monopile foundations and jacket foundations. Clarifying the types of foundations and reducing their number has a direct bearing on the scale of seabed occupation in connection with the Project, since the use of gravity foundations causing the greatest interference with the seabed and its occupation for a single foundation among all the types of foundations considered so far has been ruled out for wind power plants.

In the variant selected for implementation, the largest occupation of the bottom for a single wind turbine foundation will be for the installation of a 10-meter-diameter monopile foundation and will amount to 78.5^{m2}. Since the type of foundation for the internal offshore substation was not specified, it was assumed that the largest bottom occupation for it would occur in connection with the installation

of a gravity foundation with a base diameter of 50 m and would amount to 1,963.5^{m2}. The maximum seabed occupation for all foundations of the BIII offshore wind farm in the variant selected for implementation, i.e. 60 monopile foundations and 1 gravity foundation, will amount to 6,673.5^{m2}, a reduction of about 99% from the original preferred option. Including scour protection layers with an estimated width counted from the perimeter of each foundation of 25 m for the monopile foundation and 10 m for the gravity foundation, the bottom occupation in this variant would be 173,492.5^{m2}, about 77% less than in the original preferred variant approved in the Environmental Decision.

The above-described reduction in the maximum anticipated area of the seabed occupied by the implementation of the Project in the variant selected for implementation will result in a significant reduction in the area where seabed interference (sediment structure) will occur, as well as the destruction and permanent transformation of natural benthic habitats. Thus, the negative impacts of OWF BIII on the benthic habitats and benthic communities found in its area will be reduced.

With the reduction in the area of new hard substrate introduced into the environment due to the Project, the "artificial reef" phenomenon will be reduced. Instead, it should be emphasized that the environmental benefits of reducing interference with natural bottom habitats far outweigh any positive effects of the above-mentioned phenomenon.

In summary, the variant that is the subject of this Report will build about 70% fewer foundations than envisioned for the furthest-reaching scenario that forms the basis of the assessment in the 2015 Report - NIS 2015, and twice as many as specified in the Environmental Decision, and the use of gravity foundations under the power plants has been ruled out, which also entails correspondingly less occupation of the bottom area - as indicated in the calculations above. It is therefore considered that the Project will cause lesser impacts from both the Project in the parameters constituting the 2015 NIS and the variant approved in the Environmental Decision.

Thus, it should be considered that both the nature of the impacts does not change and their scope and intensity are significantly smaller than in the case of the variant approved by the Environmental Decision, and thus the proposed change in the parameters of implementation and operation of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.2.8. Washing out or covering up accumulations of raw materials minerals

During the operation stage, sediment movement in the bottom zone may be disturbed. The constructed foundations of the power plant are an obstacle to the displaced sediment. As a result, this can lead to the accumulation and/or leaching of sediment, resulting in the leaching of bed deposits or their backfilling.

The impacts of the exploited OWF BIII on the bottom sediments and the associated disturbance of the sediment structure, associated with foundation washout, will be negligible.

The impact of this type of disturbance on accumulations of crumb raw materials is similarly assessed. These will be at the stage of operation direct negative impacts on accumulations of crumb raw materials, local in scope, long-term, reversible, repeatable during the period of operation, with low intensity.

There will be no impacts on hydrocarbon deposits.

No measures are expected to minimize this impact at the operation stage.

The 2015 Report, which is the basis for the issuance of the current Environmental Decision, assessed the significance of this impact for the most far-reaching scenario (NIS 2015), as quoted below in Table 29, with the impacts for the variant approved in the DWA assessed as lower.

Table 30. Impact assessment of leaching or burial of mineral accumulations (mining phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Gravelly sand deposits	Medium	High	Four small potential gravel sand deposit fields have been identified within the boundaries of the future BSIII OWF and its buffer	Negligible (scale of exposure - local, duration - long-term, intensity - low)	Negligible (magnitude of impact - insignificant, importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

The variant that is the subject of this Report will build about 70% fewer foundations than envisioned for the furthest-reaching scenario that forms the basis of the assessment in the 2015 Report - NIS 2015, and twice as many as specified in the Environmental Decision, and the use of gravity foundations under the power plants has been ruled out, which is also associated with correspondingly less leaching or burial of mineral accumulations. It is therefore considered that the Project will cause lesser impacts from both the Project in the parameters constituting the 2015 NIS and from the variant approved in the DWA.

Thus, it should be considered that both the nature of the impacts does not change and their scope and intensity are smaller than in the case of the variant approved by the Environmental Decision, and thus the proposed change in the parameters of implementation and operation of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.2.9. Obstruction of access to mineral accumulations minerals

Foundations and cables belonging to the BIII offshore wind farm occupy certain areas of the seabed, hindering possible exploration, prospecting and extraction of mineral resources.

These will be at the stage of exploitation direct negative impacts on mineral deposits, local in scope, long-term, reversible, one-time, with very high (crumbly raw materials) or low (hydrocarbons) intensity.

No measures are expected to minimize this impact at the operation stage.

The 2015 Report, which is the basis for the issuance of the current Environmental Decision, assessed the significance of this impact for the most far-reaching scenario (NIS 2015), as quoted below in Table 9, with the impacts for the variant approved in the Environmental Decision assessed as lower.

Table 31. Impact assessment of obstructing access to mineral accumulations (mining phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Gravelly sand deposits	Medium	High	Four small potential gravel sand deposit fields have been	Moderate (scale of exposure - local, duration - long-term,	Small (magnitude of impact - moderate,

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
			identified within the boundaries of the future BSIII OWF and its buffer	intensity - very high)	importance of the resource - medium)
Hydrocarbon deposits	Small	Average	Two hydrocarbon exploration and appraisal licenses encroach slightly on the farm area	Negligible (scale of exposure - local, duration - long-term, intensity - low)	Negligible (magnitude of impact - insignificant, importance of the resource - low)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

The variant that is the subject of this Report will build about 70% fewer foundations than envisioned for the farthest-reaching scenario - NIS 2015 - that forms the basis of the assessment in the 2015 Report, and twice as many as specified in the Environmental Decision, and the use of gravity foundations under the power plants has been ruled out, with correspondingly less access to mineral accumulations. It is therefore considered that the Project will cause lesser impacts from both the Project in the parameters constituting the 2015 NIS and the variant approved in the Environmental Decision.

Thus, it should be considered that both the nature of the impacts does not change and their scope and intensity are smaller than in the case of the variant approved by the Environmental Decision, and thus the proposed change in the parameters of implementation and operation of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.2.10. Contamination of water bodies and bottom sediments with compounds from corrosion protection agents

Steel structures of power plant and substation foundations will corrode in the marine environment. Accordingly, appropriate protective measures will be necessary.

The most common anti-corrosion method used in the marine environment is cathodic protection. It can be implemented as galvanic or electrolytic protection.

Galvanic cathodic protection involves installing aluminum or zinc anodes on the foundations. Anodes are gradually consumed and Al or Zn passes into the water depths and accumulates in bottom sediments.

The most common protector for steel in seawater is zinc. Its current efficiency reaches 90% at the same time as its relatively low manufacturing cost. The disadvantage of zinc is the low potential difference with respect to steel, of ~0.25 V. Zinc is used as pure (99.99%, with limited Fe, Cu and Pb impurities) or as a matrix of alloys containing: Zn + 0.1÷0.15% Hg, Zn + 0.12÷0.18% Al + 0.05÷0.1% Cd, Zn + ~0.5% Al + ~0.1% Si (Surowska, 2002).

Aluminum is used only in the form of alloys: with zinc (3÷6% Zn), with tin (0.1÷1% Sn), with Zn+In, Zn+Hg, Zn+Sn. The current efficiency of these alloys is high, on the order of 80%. Aluminum alloys have the

same uses as zinc. They belong, along with zinc and its alloys, to low potential protectors (Surowska, 2002).

The advantages of the cathodic galvanic method are independence from power sources, ease of installation, the possibility of local protection and negligible impact on neighboring structures. In contrast, the most important disadvantages include the irreversible loss of anode material, the possibility of environmental contamination by protector corrosion products, limited application due to environmental resistance and low protective current.

During the initial period of operation, zinc and aluminum emissions from the anodes will not be observed. This process will continue as the years pass and the degree of damage to the protective coating on the components subject to corrosion protection. It is assumed that complete dissolution of the anodes occurs over a period of about 25 years. The metals in question will primarily pass into the water table, from which they can be precipitated and accumulated in the sediment. This is especially true for aluminum compounds, since its solubility in natural waters (with a pH of about 8) is very low. It will be largely sorbed by bottom sediments in the form of stable compounds. Zinc compounds can persist longer than aluminum in the water table because most of them are water-soluble. Zinc will be adsorbed and co-precipitated with hydrated Fe, Mn and Al oxides found in the sediments; however, this process will be slow due to the low content of clay minerals in the BII OWF area, which favor zinc adsorption (Alloway and Ayres, 1999).

Aluminum is one of the most widespread elements on Earth, found in soil, water and air. Aluminum is found in all natural waters, where it can occur in soluble and insoluble forms, in organic compounds and inorganic compounds. Its amount varies from 0.0001 to 1 $^{mg/dm3}$, in acidic waters (pH < 5) Al concentration can exceed 100 $^{mg/dm3}$ (Widlak, 2011 for: Langauer-Lewowicka, 2005; Szteke, 1993). Dissolved Al concentrations in seawater are generally low, ranging from 0.008 to 0.68 µg/l (open ocean), 0.5 to 0.68 µg/l (coastal waters) and 0.6 to 0.9 µg/l (North Sea) (Kirchgeorg et al., 2018 after Angel et al., 2015).

For marine structures, Al-based anodes are mainly used for galvanic cathodic protection, which, depending on the specific alloy, manufacturer and standard used, also contain Zn (2.5-5.75%) and In (0.015-0.04%). The amount of anodic material required to protect offshore wind farm steel structures from corrosion depends primarily on the type of foundations (their surfaces), the planned service life (e.g., at least 25 years), seawater conditions, the placement of anodes, and the possible use of additional corrosion protection methods, such as epoxy or polyurethane-based coatings. Chemical emissions are similar to the amount of anode material used, assuming that the bulk of it will be "used up" within 25 years of operation and enter the marine environment (Kirchgeorg et al., 2018). Simplified calculations of the necessary amounts of Al-Zn-In anode material made based on DNVGL-RP-B401 (2017) by Kirchgeorg et al. were used to estimate the potential Al and Zn emissions associated with the Project for various foundation designs used in offshore wind farms, with and without additional coating. (2018). According to these calculations, for foundations without additional coating, the required amount of anodic material ranges from 13.0 Mg (monopal) to 32.0 Mg (tripod), while the additional coating reduces it significantly to 6.0 and 10.7 Mg, respectively. It should be noted that the indicated calculations do not take into account additional factors, such as the distribution of anodes throughout the structure, which must be taken into account when designing corrosion protection and which may change the total number of anodes required. The results of the estimation of expected emissions from corrosion protection for the Project are presented in the table below.

Table 32. The amount of Al and Zn that could potentially be released to the environment during the 25-year operation of the Project with the parameters envisioned in the 2015 NIS and in the currently proposed

implementation option as a result of the application of galvanic cathodic corrosion protection, assuming 5% Zn content in the Al-Zn-In anode material in the most far-reaching scenario.

Type of foundation	Additional protective coating	Mass of Al-In-Zn anode material, including 5% Zn [Mg]	The amount of Al and Zn released		
			1 foundation, the amount of element released over the life of the farm (25 years)	The most far-reaching scenario for NIS 2015 (208 foundations), the amount of element released annually by the entire farm	The most far-reaching scenario for the currently proposed implementation variant (61 foundations), the amount of element released annually by the entire farm
Monopal	not	approx. 13,0	approx. 12.35 Mg of Al approx. 0.65 Mg Zn	approx. 101.76 Mg of Al approx. 5.36 Mg Zn	approx. 30.13 Mg of Al approx. 1.59 Mg Zn
	yes	approx. 6,0	approx. 5.70 Mg Al approx. 0.30 Mg Zn	approx. 46.97 Mg of Al approx. 2.47 Mg Zn	approx. 13.91 Mg of Al approx. 0.73 Mg Zn
Jacket	not	approx. 22,5	approx. 21.38 Mg of Al approx. 1.13 Mg Zn	approx. 176.13 Mg of Al approx. 9.27 Mg Zn	approx. 52.16 Mg of Al approx. 2.75 Mg Zn
	yes	approx. 7,5	approx. 7.13 Mg Al. approx. 0.38 Mg Zn	approx. 58.71 Mg of Al approx. 3.09 Mg Zn	approx. 17.39 Mg of Al approx. 0.92 Mg Zn
Tripod	not	approx. 32,0	approx. 30.40 Mg of Al approx. 1.60 Mg Zn	approx. 250.50 Mg of Al approx. 13.18 Mg Zn	approx. 74.18 Mg of Al approx. 3.90 Mg Zn
	yes	approx. 10,7	approx. 10.17 Mg of Al approx. 0.54 Mg Zn	approx. 83.76 Mg of Al approx. 4.41 Mg Zn	approx. 24.80 Mg Al approx. 1.31 Mg Zn

Source: own compilation based on Kirchgeorg et al. (2018).

The estimate made shows that the largest annual emissions of Al and Zn resulting from the Project will occur when tripod foundations are used.

The estimated Zn emissions associated with the Project with the parameters envisioned in the 2015 NIS, amounting to approximately 13.18 Mg/year in the furthest scenario (tripod foundations, without additional coating), are negligible in relation to the load of this element entering the Baltic Sea with rivers each year. In 2006, a total of 3,157.3 Mg of Zn was discharged into the Baltic Sea with water, 256.65 Mg of which came from Poland (HELCOM, 2011). The projected Zn emissions in the farthest-reaching scenario thus represent only about 0.4% of this load. By comparison, for the currently proposed Project variant in the farthest-reaching scenario, estimated Zn emissions are about 3.9 Mg/year, representing about 0.1% of the element's load discharged with water into the Baltic Sea in 2016.

The use of Zn-based anodes for the Project would increase the total annual emissions from corrosion protection, due to their lower current capacity compared to Al-based anodes, and thus the need for more anode material. For this type of anode, 99% of the emissions are Zn. Although Zn anodes are technically suitable for offshore wind farms, the larger number required causes design difficulties. Therefore, Zn anodes are not currently used in offshore wind farms in the German exclusive economic zone (Kirchgeorg et al., 2018).

Recently, there was a report on the use of metallic coating (Al, 350 µm) applied by thermal spraying in combination with organic coatings for a wind farm in the Baltic Sea as an alternative technique to avoid the use of anodes and thus reduce metal emissions (Kirchgeorg et al., 2018).

If a decision is made to use galvanic cathodic protection for the Project, additional protective coatings or other analogous solutions will be included in the design to reduce the amount of anodic material required, and thus also the emissions from this protection. Detailed solutions in the subject area will be determined at the design stage of the Project's corrosion protection.

In electrolytic cathodic protection, the protected object becomes the cathode of an electrolytic cell supplied with DC current from an external source. The anode used in this circuit is mostly insoluble. Among the most durable anode materials used in this method are platinum and titanium electrodes coated with a 2-3 µm layer of platinum. With electrolytic cathodic protection, no impact on water quality or sediment is observed.

If electrolytic cathodic protection is used, emissions of metals (Al, Zn) to the aquatic environment will not be observed due to the use of non-degradable anodes - therefore, this impact has not been assessed.

No measures are expected to minimize this impact at the operation stage.

Pollution of the environment with Al or Zn released during operation is a direct, negative impact of local extent, long-term, irreversible, permanent during the period of operation, of medium intensity.

An assessment of the significance of this impact for the most far-reaching scenario, which was evaluated in the 2015 Report, is presented in Table 32, below.

Table 33. Impact assessment involving contamination of seawater and bottom sediments with zinc or aluminum from corrosion protection agents (operational phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Marine waters	Medium	Average	During the operation of the farm, there will be emissions of Zn or Al used in anodes used for corrosion protection of steel structures	Small (scale of exposure-local, duration-long term, intensity-medium)	Small (magnitude of impact - low, importance of the resource - medium)
Seabed / bottom sediments	Large (areas P1 and P3)	Low			Small (magnitude of impact - low, importance of the resource - high)
	Medium (areas P2, P4 and P5)	Average			Small (magnitude of impact - low, importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

In the currently proposed variant, there has been a reduction in the total number of foundations and the types of foundations on which wind turbines can be placed. In this variant, only monopile and jacket type foundations can be used in the Project for the installation of wind turbines. If galvanic cathodic protection is used, reducing the number of BIII OWF foundations, as well as excluding tripod-type foundations (which potentially require the largest number of anodes) from further consideration for wind power plant siting, will reduce the total amount of anode material required, and thus emissions to the marine environment. The impact in this regard will therefore remain insignificant.

In summary, the variant that is the subject of this Report will build about 70% fewer foundations than envisioned for the furthest-reaching scenario that forms the basis of the assessment in the 2015 Report - NIS 2015, and twice as many as specified in the Environmental Decision, which also entails the use of a correspondingly smaller number of anodes for corrosion protection, and thus fewer emissions. The calculations presented showed that with the application of an additional protective coating of the amounts of Zn and Al, additional reductions in the elements released into the environment will be achieved, and thus the project will cause lower impacts both from the Project in the parameters constituting the NIS and from the variant approved in the Environmental Decision.

Thus, it should be considered that both the nature of the impacts does not change and their scope and intensity are smaller than in the case of the variant approved by the Environmental Decision, and thus the proposed change in the parameters of implementation and operation of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.2.11. Change in temperature of water and sediments

The electric current, flowing through the power cable, causes it to heat up, caused by power losses on the resistance, according to Joule's law. With the increase in cable temperature above ambient temperature, heat transfer to the surrounding environment begins.

Accurate quantification of the heat given off is difficult, as there are phenomena of heat conduction, lift and radiation, subject to different physical laws (Stiler et al., 2006).

A 1°C increase in sediment temperature can cause a 10-fold increase in bacterial activity, which can accelerate and increase organic matter decomposition processes. This situation can also promote the decomposition of organic nitrogen, which becomes more available due to increased and accelerated mineralization to inorganic compounds (the amount of inorganic nitrogen forms, which is generally well soluble in water, increases). An increase in temperature can also cause a decrease in the oxygen content of the water (Miętus, Sztobryn, 2011; Zalewska et al, 2012; Ramsing and Gundersen, 2012) and promote the transformation of ammonium nitrogen compounds contained in water and sediment into a gaseous form, which is harmful to living organisms (Falkowska et al, 1999). At a temperature of 5°C and a pH of 8.2, about 2% of ammonium compounds convert to the gaseous form, while at 25°C about 8% of ammonium compounds convert to the gaseous form (about a 4-fold increase). The contribution of the different forms of ammonia is very important because of fish and other marine organisms, for which the gaseous form ($_{NH3}$) is toxic, unlike the $^{NH4+}$ ion (Falkowska et al., 1999). According to Directive 76/464/EEC, the lethal concentration of ammonia for rainbow trout is 5 $^{mg\text{-}dm\text{-}3}$, and for crustaceans is 8 $^{mg\text{-}dm\text{-}3}$.

Heating of the bottom sediment and interstitial waters (waters filling the spaces between sand grains in the sediment) can also promote (intensify the processes of) the passage of metals from the sediment to the water table and accelerate the processes of decomposition (degradation) of organic contaminants in the bottom sediment. An increase in sediment temperature can also adversely affect the condition of benthic (benthic) organisms (OSPAR 2008-3). In addition, nutrient and oxygen content may be altered as a result of the disrupted temperature profile (Worzyk, 2009).

At the Nysted Offshore Wind Farm, the temperature rise emitted by a transmission cable (132 kV) buried at a depth of 1 m, did not exceed 1.4°C in the layer 20 cm above the cable, and already at the bottom surface, temperature changes were invisible (Merck 2009). This cable was buried in gravelly sediment, which promotes much greater heat loss in the interstitial spaces between sediment grains than in fine-grained sediment (Merck 2009). Both of these sediment types are common in the area of the planned BII OWF. It should be assumed that the heat dissipation (24 W/m, on the cable surface) emitted by the internal 33 or 66 kV cables belonging to OWF BIII will be less (or at most similar) to that recorded at the Nysted offshore wind farm. In general, the benthic fauna is naturally adapted to large seasonal temperature changes and is not sensitive or shows very low sensitivity to a 2°C (2 K) temperature increase (Birklund 2009). According to standards proposed by the German Federal Agency for Nature Conservation, the temperature increase due to heat emission of the transmission cable in the layer 20 cm below the bottom surface, which is biologically the most active habitat for infauna, must not exceed 2 K (2°C). According to Royal Haskonng DHV (2014) technical assumptions, heat emission over MIP cables in the sediment will be local (from a few cm to a maximum of 1 m), and the effect will be imperceptible if the cable is buried deeper than 1 m. Therefore, no significant impact of this parameter on the abiotic environment is expected.

Therefore, minimization measures are not required.

Heat emission from cables is a direct, negative impact of local extent, long-term, irreversible, permanent during the period of operation, of medium intensity.

The 2015 Report, which is the basis for the issuance of the current Environmental Decision, assessed the significance of this impact for the most far-reaching scenario (NIS 2015), as quoted below in Table 33, with the impacts for the variant approved in the Environmental Decision assessed as lower.

Table 34. Impact assessment involving water and sediment temperature change (operational phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Seabed / bottom sediments	Large (areas P1 and P3)	Average	During the operation of the farm, there will be an increase in the temperature of the interstitial waters and sediments due to the heating of the cables	Negligible (scale of exposure - local, duration - long-term, intensity - low)	Small (magnitude of impact - insignificant, importance of the resource - high)
	Medium (areas P2, P4 and P5)			Negligible (scale of exposure - local, duration - long-term, intensity - low)	Negligible (magnitude of impact - insignificant, importance of the resource - medium)
Marine waters	Medium			Small (scale of exposure - local, duration - long-term, intensity - medium)	Small (magnitude of impact - low, importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

The variant that is the subject of this Report will build about 70% fewer foundations than envisioned for the furthest-reaching scenario that forms the basis of the assessment in the 2015 Report - NIS 2015, and twice as many as specified in the Environmental Decision, and the use of gravity foundations under the power plants has been ruled out, but at this stage it is assumed that the total length of cable sections

for all variants will be the same. In the variant selected for implementation, only the lengths of individual cable sections will increase, due to the greater distances between power plants. The result of the impact assessment is therefore convergent in all the parameters of the Project considered.

Thus, it should be considered that both the nature of the impacts remain unchanged, and their scope and intensity are comparable as in the case of the variant approved by the Environmental Decision, and thus the proposed change in the parameters of implementation and operation of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.2.12. Changes in the regime of currents seas

The impact of operating wind turbines on hydrological conditions manifests itself primarily in the modification of the flow field of marine currents. These currents, encountering an obstacle in the form of a support structure, flow around it. Then in the immediate vicinity of the structure there is a change in the velocity and direction of flow and water pressure. This results in a local increase in water velocity due to the narrowing of the flow stream and the formation of turbulence around the structure. Particularly important, and difficult to predict, is the formation of turbulence around the structure. Vortices can be formed both on the downstream side and directly in front of the obstacle. The range of influence of the substructure on the flow of water in the seabed is equal to only a few diameters of the structure. In contrast, the distances between individual power plants are on the order of several hundred meters. This means that no overlap is expected between these impacts.

There are several factors that can affect the way the water flow field is modified due to the installation of wind power plants. Here it is necessary to distinguish first of all:

- the number of wind turbines, the distance between them and how they are deployed;
- the dimensions and shape of the individual towers;
- type and dimensions of foundations;
- flow field characteristics (velocities, dominant directions, etc.);
- bathymetry with special attention to surface gradients and natural obstacles.

The assessment of the wind farm's impact of inducing changes in the regime of sea currents was based on the analyses contained in the hydrographic modeling report performed for the Central Baltic offshore wind farm III (SMDI, 2015). The aforementioned hydrographic report modeled the changes in the regime of sea currents that will occur after the construction of the BIII OWF. The analysis was performed for all project alternatives considered.

The simulation was performed for the months of January and July, for 5 control points located inside and outside the farm area. As it shows, there will be a minimal reduction in the speed of the flow of sea currents inside the farm after it is built. These will be velocity changes of up to about 0.5 cm/s in July and up to 1 cm/s in January, and these values vary very little for the different variants analyzed. Meanwhile, average flow velocities recorded by the Maritime Institute in Gdansk during year-long surveys at two measurement points in the farm area ranged from 8.44 to 17.73 cm/sec. The reduction in the current speed of currents inside the wind farm will be offset by a slight increase in their speed outside the farm. The sensitivity of marine waters in the area of the farm was assessed as very low (negligible).

The impact itself during the operation of the farm will be no different from the impact at the final stage of construction (i.e., when all foundations are placed).

No measures are expected to minimize this impact at the operation stage.

Changes in the regime of sea currents at the stage of operation of the farm is a direct, negative impact of local scope, long-term (at the stage of operation), irreversible, low intensity. The 2015 Report, which is the basis for the issuance of the current Environmental Decision, assessed the significance of this impact for the most far-reaching scenario (NIS 2015), as quoted below in Table 34, with the impacts for the variant approved in the Environmental Decision assessed as lower.

Table 35. Impact assessment of changing the regime of sea currents (operational phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Marine waters	Medium	Very low (negligible)	Operation of the wind farm foundations will affect the regime of sea currents in the area of the project	Negligible (scale of exposure - local, duration - long-term, intensity - low)	Negligible (magnitude of impact - insignificant, importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

The variant that is the subject of this Report will build about 70% fewer turbines, and thus foundations, than envisioned for the farthest-reaching scenario that forms the basis of the assessment in the 2015 Report - NIS 2015, and twice as many as specified in the Environmental Decision, and the use of gravity foundations under the power plants has been ruled out, so the potential impact on ocean currents will be reduced proportionately. It is therefore considered that the Project will cause lesser impacts from both the Project in the parameters constituting the 2015 NIS and the variant approved in the Environmental Decision.

Thus, it should be considered that both the nature of the impacts does not change and their scope and intensity are smaller than in the case of the variant approved by the Environmental Decision, and thus the proposed change in the parameters of implementation and operation of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.2.13. Damping ripples

The impact of operating wind turbines on hydrological conditions is also manifested in the attenuation of wind waves, as detailed in section 9.1.11 of this section. The impact itself during the operation of the farm will be no different from the impact at the final stage of construction (i.e., when all the foundations are in place).

No measures are expected to minimize this impact at the operation stage.

Wave attenuation during the operation stage of the farm is a direct, negative impact of local extent, long-term, irreversible, of medium intensity.

An assessment of the significance of this impact to the NIS, which was assessed in the 2015 Report, is shown in Table 35, below.

Table 36. Impact assessment involving surface wave attenuation (operational phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Marine waters	Medium	Very low (negligible)	The operation of the wind farm foundations will affect surface wave action in the project area	Negligible (scale of exposure - local, duration - long-term, intensity - low)	Negligible (magnitude of impact - insignificant, importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

The variant that is the subject of this Report will build about 70% fewer turbines, and thus foundations, than envisioned in the 2015 NIS, and twice as many as specified in the Environmental Decision, so it will reduce its impact on wave action proportionately. It is therefore considered that the project will cause lesser impacts from both the 2015 NIS and the variant approved in the Environmental Decision.

Thus, it should be considered that both the nature of the impacts does not change and their scope and intensity are smaller than in the case of the variant approved by the decision, and thus the proposed change in the parameters of implementation and operation of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.2.14. An increase in the amount of suspended solids in the water

Minor violations of the structure of the bottom sediments that will occur at the stage of operation, primarily associated with anchoring of ships and replacement of cable fragments (e.g., due to damage to the cable), will cause an impact consisting in a reduction in water transparency, caused by the floating of suspended solids in the water depths (water turbidity), but not affecting the structure and functioning of the resource (not causing changes).

There is no need for minimization measures.

The increase in the amount of suspended solids in water at the stage of operation of the farm is a direct, negative impact of point in time, temporary, reversible, repeatable during the period of operation, with low intensity.

An assessment of the significance of this impact in the 2015 Report, the basis for the current Environmental Decision, was made for the most far-reaching scenario (NIS 2015), as shown in Table 36, below.

Table 37. Impact assessment of increase in suspended solids in water (operational phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Marine waters	Medium	Very low (negligible)	During the operation of the farm there will be violations of the structure of the bottom	No change - water turbidity not affecting the structure and functioning of the resource	No change

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
			sediments, resulting in a slight turbidity of the water		

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

The variant that is the subject of this Report will build about 70% fewer turbines than envisioned for the furthest-reaching scenario - NIS 2015 - that forms the basis of the assessment in the 2015 Report, and twice as many as specified in the Environmental Decision, while the total cable length will remain unchanged. The level of potential turbidity in the water may decrease, as a result of a reduction in the number of anchor vessels arriving for turbine maintenance. It is therefore considered that the Project will cause lesser impacts from both the Project in the parameters constituting the 2015 NIS and the variant approved in the Environmental Decision.

Thus, it should be considered that both the nature of the impacts does not change and their scope and intensity are smaller than in the case of the variant approved by the Environmental Decision, and thus the proposed change in the parameters of implementation and operation of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.2.15. Impacts cumulative

Assumptions for the analyses of cumulative impacts of the BIII OWF as it will be implemented after the amendment of the Environmental Decision and other projects on the environment are presented in Section 3.2. On the other hand, a broad description regarding this issue is provided in Section 13 of Volume II of the EIA report.

The 2015 Report, which formed the basis for the impact assessment for the Project in the parameters approved in the Environmental Decision, assumed two cumulative impact scenarios.

According to the first scenario, it was assumed that between 2021 and 2025, a total of 150 power plants and associated infrastructure would be operated under the BSIII offshore wind farm and Baltica 3 offshore wind farm projects. Thus, it was considered that in the above scenario, the level of cumulative impacts on abiotic environmental elements would be only 75% of the level analyzed in the 2015 Report for the set of parameters of the Project constituting the 2015 NIS.

After 2026, the number of total power plants in operation with connection infrastructure may increase to 375 if additional connection conditions are obtained under the BIII OWF. Accordingly, the level of cumulative impacts on abiotic environmental elements will be 87.5% higher than the level analyzed in the 2015 Report for the set of parameters of the Project constituting the 2015 NIS.

It was also noted that most of the impacts described in Chapter 9 will not be cumulative, due to the scope being limited to the site of the foundation in question or its immediate surroundings.

Potential accumulation may include the release of zinc from corrosion protection, seabed occupation, disturbance of the bottom sediment structure, thereby dispersing suspended solids and releasing pollutants and nutrients. However, the significance of these impacts was assessed to be negligible or low, while that of seabed occupation was assessed to be moderate.

The variant that is the subject of this Report will build about 70% fewer power plants than envisioned for the furthest-reaching scenario that forms the basis of the assessment in the 2015 Report - NIS 2015, and twice as many as specified in the Environmental Decision, and the use of gravity foundations under the power plants has been excluded, so that even in the case of cumulative impacts with those associated with the operation of other power plants, the total impacts will be less than those assessed in the 2015 Report. It is therefore considered that the Project will contribute less to cumulative impacts, both from the Project in the parameters constituting the 2015 NIS and from the variant approved in the Environmental Decision.

Thus, it should be considered that both the nature of the impacts does not change and their scope and intensity are smaller than in the case of the variant approved by the Environmental Decision, and thus the proposed change in the parameters of implementation and operation of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.3. Stage decommissioning

The decommissioning phase will most likely see the removal of most of the farm's facilities from the seabed, in accordance with international regulations for installations and structures in marine areas (United Nations Convention on the Law of the Sea - UNCLOS).

These regulations set conditions for the removal of elements and installation of wind farms in the areas of the continental shelf and the exclusive economic zone. Decommissioning work should be carried out in such a way that it does not impede navigation or adversely affect the marine environment.

The standards also define exceptional situations in which there is no obligation to completely remove infrastructure elements. It is possible to leave such objects when:

- the weight of the foundation in the air exceeds 4,000 tons or is located at a depth of more than 100 meters, provided that it does not cause hindrance to the use of marine areas by other industries;
- decommissioning of elements is technically impossible or too costly;
- there is a threat to the lives of personnel decommissioning the wind farm;
- decommissioning entails an unacceptable risk of pollution of the marine environment.

In some locations, such as straits or archipelagic waters used for international shipping, it is necessary to completely remove installations and structures of structures, with no exceptions.

If some elements are left on the seabed, appropriate studies should be conducted to determine whether the farm's remains will not interfere with ship traffic and will not have a negative impact on biotic and abiotic elements of the environment. Make sure that the parts of the structure left behind do not begin to move under the influence of waves, tides, currents or storm surges, causing a hazard to shipping.

The following environmental impacts are expected to occur during decommissioning of the BIII OWF:

- disruption of sediment structure;
- the release of pollutants and nutrients from the sediment into the water body;
- disruption of the bottom structure;

- change in bottom morphology;
- seabed area occupation;
- leaching out or burying mineral accumulations;
- making access to mineral accumulations more difficult;
- changing the regime of sea currents;
- wind wave attenuation;
- water turbidity.

Unplanned impacts may also occur during decommissioning of the farm, which are described in detail in Section 12 of Volume II of the Report and in Chapter 11 of this section.

9.3.1. Structural disorders sediments

Works related to decommissioning of the entire farm or its individual facilities (removal of foundations and cables, anchoring of ships) will involve resuspension of surface sediments and their re-deposition.

In areas where there is no loose sediment on the surface or the layer is thin (P1, P3), the impact will be of little significance. In areas with a thicker layer of sands or silty clay sediments (P2, P4, P5), the agitated sediment will float longer.

Disturbance of bottom sediment structure is, at the stage of decommissioning, a direct negative impact of local extent, short-term, reversible, recurrent (during the period of decommissioning), with low to medium intensity (depending on the area).

During the decommissioning phase, no measures are expected to minimize this impact.

The 2015 Report, which is the basis for the issuance of the current Environmental Decision, assessed the significance of this impact for the most far-reaching scenario (NIS 2015), as quoted below in Table 37, with the impacts for the variant approved in the Environmental Decision assessed as lower.

Table 38. Impact assessment involving disturbance of bottom sediment structure (decommissioning phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Seabed / bottom sediments	Large (areas P1 and P3)	Low	During the decommissioning of the farm, the structure of the bottom sediments will be disturbed	Negligible (scale of exposure - local, duration - short-term, intensity - low)	Small (magnitude of impact - insignificant, importance of the resource - high)
	Medium (areas P2, P4 and P5)	Medium (areas P2 and P4) or high (area P5)		Negligible (scale of exposure - local, duration - short-term, intensity - medium to high)	Negligible (magnitude of impact - insignificant, Importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

In the variant that is the subject of this Report, about 70% fewer foundations will be built (and thus potentially decommissioned) than envisioned for the furthest-reaching scenario - NIS 2015 - that forms the basis of the assessment in the 2015 Report, and twice as many as specified in the Environmental Decision, and the use of gravity foundations under the power plants has been ruled out, so the disturbance of the bottom sediment structure will occur over a correspondingly smaller area. It is therefore considered that the Project will cause lesser impacts from both the Project in the parameters constituting the 2015 NIS and the variant approved in the Environmental Decision.

Thus, it should be considered that both the nature of the impacts remains unchanged, and their scope and intensity are smaller than in the case of the variant approved by the Environmental Decision, and thus the proposed change in the parameters of the project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.3.2. Release of pollutants and nutrients from the sludge into the water body water

As a result of disturbance during the decommissioning of the farm, bottom sediments may release pollutants and nutrients from them. This process is described in more detail in section 9.1.2 of this section.

In areas P1 and P3, where there is no loose sediment on the surface or the layer is thin (the northern and northwestern parts of the field), the impact will be of little significance. In areas with a thicker layer of sands or silty clay sediments (P2, P4 and P5 - central, eastern and southwestern parts), the agitated sediment will float longer.

During the excavation of foundations and cables from the bottom, the impact on water and sediment quality will be similar to the stage of foundation placement on the bottom during the construction phase. If the foundations are left in the bottom sediment, the impact on sediment and water quality will be negligible.

During the decommissioning phase, no measures are expected to minimize this impact.

The release of pollutants and nutrients from the sludge into the water body is a direct, negative impact at the decommissioning stage that is regional in scope, short-term, reversible, repeatable, with medium to high intensity, depending on the location.

The 2015 Report, which is the basis for the issuance of the current Environmental Decision, assessed the significance of this impact for the most far-reaching scenario (NIS 2015), as quoted below in Table 38, with the impacts for the variant approved in the Environmental Decision assessed as lower.

Table 39. Impact assessment involving the release of pollutants and nutrients from sediment into the water body (decommissioning phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Seabed / bottom sediments	Large (areas P1 and P3)	Low	During the decommissioning of the farm, there will be a release of	Negligible (scale of exposure - regional, duration - short-term, intensity - low)	Small (magnitude of impact - insignificant, importance of

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
			pollutants and nutrients in the sediment into the water body		the resource - high)
	Medium (areas P2, P4 and P5)	Medium (areas P2 and P4) or high (area P5)		Small (scale of exposure - regional, duration - short-term, intensity - medium to high)	Small (magnitude of impact - low, importance of the resource - medium)
Marine waters	Medium	Average		Small (scale of exposure - regional, duration - short-term, intensity - medium to high)	Small (magnitude of impact - low, importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

In the variant that is the subject of this Report, about 70% fewer foundations will be built and then decommissioned than envisaged in the case of the most far-reaching scenario forming the basis of the assessment in the 2015 Report - NIS 2015, and twice as many as specified in the Environmental Decision, and the use of gravity foundations under the power plants has been ruled out, so there will be a smaller area of disturbed sediment, and consequently a correspondingly smaller amount of pollutants and nutrients released from it. It is therefore considered that the Project will cause lesser impacts from both the Project in the parameters constituting the 2015 NIS and the variant approved in the Environmental Decision.

Thus, it should be considered that both the nature of the impacts does not change and their scope and intensity are smaller than in the case of the variant approved by the Environmental Decision, and thus the proposed change in the parameters of implementation and operation of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.3.3. Structural disorder bottom

Disturbance of the bottom structure will occur during construction activities, as described in detail in section 9.1.4 of this section, but most of them are continuous changes (once the structure is disturbed, it will not return to its original state), so they will remain even after the decommissioning of the farm, such as changes in the bottom associated with driving foundation piles into it, as they will not be pulled out of the bottom, but will most likely be cut off at a depth of about 3 m below its surface.

No measures are expected to minimize this impact.

Disturbance of the bottom structure is a direct, negative impact of local scope, permanent, long-term and irreversible at the stage of decommissioning. The intensity of the impact was determined to be low.

The 2015 Report, the basis for the issuance of the current Environmental Decision, assessed the significance of this impact for the most far-reaching scenario (NIS 2015), as quoted below in Table 39, with impacts for the variant approved by the Environmental Decision assessed as less.

Table 40. Impact assessment involving disturbance of bottom structure (decommissioning phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Seabed	Large (areas P1 and P3)	Medium or high	During the decommissioning of the farm, the bottom structure will be breached	Negligible (scale of exposure - local, duration - long-term, intensity - low)	Small (magnitude of impact - insignificant, importance of the resource - high)
	Medium (areas P2, P4 and P5)	Medium or high		Negligible (scale of exposure - local, duration - long-term, intensity - low)	Negligible (magnitude of impact - insignificant, importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

The variant that is the subject of this Report will build about 70% fewer foundations than envisioned for the furthest-reaching scenario that forms the basis of the assessment in the 2015 Report - the NIS 2015, and twice as many as specified in the Environmental Decision, and the use of gravity foundations under the power plants has been excluded, so the disruption of the bottom structure associated with their removal will occur in a correspondingly smaller number of locations and over a smaller area. It is therefore considered that the Project will cause lesser impacts from both the Project in the parameters constituting the 2015 NIS and the variant approved in the Environmental Decision.

Thus, it should be considered that both the nature of the impacts does not change and their scope and intensity are smaller than in the case of the variant approved by the Environmental Decision, and thus the proposed change in the implementation and operation of the Parameters of the project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.3.4. Change in morphology fundus

During the decommissioning stage of the farm, there will be a change in the morphology (shape) of the seabed. If pile foundations are removed, holes remain on the seabed. The process of backfilling due to wave or storm surges, or suspended sedimentation, will take a long time. It will also depend on the type of substrate. In areas with clayey formations (P1, P3), the process takes much longer due to the low susceptibility to dilution. It will be faster in areas of loose sediment (P2, P4, P5).

No measures are expected to minimize this impact.

The change in bottom morphology during the decommissioning stage is a direct, negative impact of local extent, medium- to long-term, reversible, one-time, of medium to high intensity.

An assessment of the significance of this impact to the NIS, which was evaluated in the 2015 Report, is presented in Table 40, below.

Table 41. Impact assessment involving alteration of bottom morphology (decommissioning phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Seabed / bottom sediments	Large (areas P1 and P3)	Low	During the decommissioning of the farm, there will be a change in the morphology of the bottom	Moderate (scale of exposure - local, duration - long-term, intensity - high)	Moderate (magnitude of impact - moderate, Importance of the resource - high)
	Medium (areas P2, P4 and P5)	Medium (areas P2 and P4) or high (area P5)		Small (scale of exposure - local, duration - medium-term, intensity - medium to high)	Small (magnitude of impact - insignificant, importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

The variant that is the subject of this Report will construct about 70% fewer foundations than envisioned for the furthest-reaching scenario that forms the basis of the assessment in the 2015 Report - NIS 2015, and twice as many as specified in the Environmental Decision, and the use of gravity foundations under the power plants has been ruled out, which entails less change in bottom morphology during their decommissioning. It is therefore considered that the Project will cause lesser impacts from both the Project in the parameters constituting the 2015 NIS and the variant approved in the Environmental Decision.

Thus, it should be considered that both the nature of the impacts does not change and their scope and intensity are smaller than in the case of the variant approved by the Environmental Decision, and thus the proposed change in the parameters of implementation and operation of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.3.5. Occupation of the seabed area seabed

If some elements or entire foundations are left on the bottom during the decommissioning stage, it will be permanently occupied. Pile foundations will be removed to a depth of about 3 meters below the bottom surface. The elements left behind will deteriorate the quality of the bottom. Heavy gravity foundations, due to their weight, are likely to remain entirely on the seabed.

No measures are expected to minimize this impact at the operation stage.

Seabed occupation in the event that foundations and cables are left in the seabed during the decommissioning phase is a direct, negative, permanent, reversible, long-term impact of local scope. The intensity of the impact in the case of leaving gravity foundations on the seabed was assessed as high, and in the case of using left foundations as low or medium.

The 2015 Report, which is the basis for the issuance of the current Environmental Decision, assessed the significance of this impact for the most far-reaching scenario (NIS 2015), as quoted below in Table 41, with the impacts for the variant approved in the Environmental Decision assessed as lower.

Table 42. Impact assessment involving seabed occupation (decommissioning phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Seabed / bottom sediments	Large (areas P1 and P3)	Low	If all or part of the farm's facilities are left in the decommissioning stage, they will permanently occupy the seabed	Moderate (scale of exposure - local, duration - long-term, intensity - high)	Moderate (magnitude of impact - moderate, importance of the resource - high)
	Medium (areas P2, P4 and P5)			Moderate (scale of exposure - local, duration - long-term, intensity - high)	Small (magnitude of impact - moderate, importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

The variant that is the subject of this Report will construct about 70% fewer foundations than envisioned for the furthest-reaching scenario that forms the basis of the assessment in the 2015 Report - NIS 2015, and twice as many as specified in the Environmental Decision, and the use of gravity foundations under the power plants has been ruled out, which also entails correspondingly less occupation of the bottom surface in case the foundations or parts of them have to be left in the bottom during decommissioning. It is therefore considered that the Project will cause lesser impacts from both the Project in the parameters constituting the 2015 NIS and the variant approved in the Environmental Decision.

Thus, it should be considered that both the nature of the impacts does not change and their scope and intensity are smaller than in the case of the variant approved by the Environmental Decision, and thus the proposed change in the parameters of implementation and operation of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.3.6. Washing out or covering up accumulations of raw materials minerals

During the decommissioning of the BIII OWF, work will be carried out to dismantle the various elements of the farm. They can cause backfilling or leaching of sediments. A positive impact, however, will be to allow access to mineral accumulations by freeing up the previously occupied bottom area by foundations (if these are removed).

These will be at the decommissioning stage direct negative impacts on crumbling raw materials, local in scope, short-term, reversible, repeatable during the decommissioning period, with very high intensity.

There will be no impacts on hydrocarbon deposits.

No measures are expected to minimize this impact.

The 2015 Report, which is the basis for the issuance of the current Environmental Decision, assessed the significance of this impact for the most far-reaching scenario (NIS 2015), as quoted below in Table 42, with the impacts for the variant approved in the Environmental Decision assessed as lower.

Table 43. Impact assessment of leaching or burial of mineral accumulations (decommissioning phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Gravelly sand deposits	Medium	High	Four small potential gravel sand deposit fields have been identified within the boundaries of the future OWF BIII and its buffer	Small (scale of exposure - local, duration - short-term, intensity - very high)	Small (magnitude of impact - low, importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

The variant that is the subject of this Report will build about 70% fewer foundations than envisioned for the farthest-reaching scenario that forms the basis of the assessment in the 2015 Report - NIS 2015, and twice as many as specified in the Environmental Decision, and the use of gravity foundations under the power plants has been ruled out, which is also associated with correspondingly less leaching or burial of mineral accumulations during decommissioning of the farm. It is therefore considered that the Project will cause lesser impacts from both the Project in the parameters constituting the 2015 NIS and the variant approved in the Environmental Decision.

Thus, it should be considered that both the nature of the impacts does not change and their scope and intensity are smaller than in the case of the variant approved by the Environmental Decision, and thus the proposed change in the parameters of implementation and operation of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.3.7. Obstruction of access to mineral accumulations minerals

During the decommissioning phase, a decision may be made not to remove some of the farm facilities, including foundations, for the reasons described at the beginning of Section 9.3 of this section. In such a situation, it will permanently hinder access to raw material accumulations even after the decommissioning of the investment.

No measures are expected to minimize this impact.

Obstruction of access to mineral accumulations during the decommissioning stage is a direct, negative impact of local scope, permanent, long-term, irreversible, one-time, with intensity ranging from low to very high.

An assessment of the significance of this impact to the NIS, which was evaluated in the 2015 Report, is shown in Table 43, below.

Table 44. Impact assessment of obstructing access to mineral accumulations (decommissioning phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Gravelly sand deposits	Medium	High	Four small potential gravel sand deposit	Moderate (scale of exposure - local, duration -	Small (magnitude of impact -

			fields have been identified within the boundaries of the future OWF BIII and its buffer	long-term, intensity - very high)	moderate, importance of the resource - medium)
Hydrocarbon deposits	Small	Average	Two hydrocarbon exploration and appraisal licenses encroach slightly on the farm area	Negligible (scale of exposure - local, duration - long-term, intensity - low)	Negligible (magnitude of impact - insignificant, importance of the resource - low)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

The variant that is the subject of this Report will build about 70% fewer foundations than envisioned for the furthest-reaching scenario that forms the basis of the assessment in the 2015 Report - NIS 2015, and twice as many as specified in the Environmental Decision, and the use of gravity foundations under the power plants has been ruled out, which is also associated with correspondingly less difficulty in accessing raw material accumulations during and after decommissioning of the farm. It is therefore considered that the Project will cause lesser impacts from both the Project in the parameters constituting the 2015 NIS and the variant approved in the Environmental Decision.

Thus, it should be considered that both the nature of the impacts does not change and their scope and intensity are smaller than in the case of the variant approved by the Environmental Decision, and thus the proposed change in the parameters of implementation and operation of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.3.8. Changes in the regime of currents seas

If during the decommissioning of the hydrotechnical infrastructure at the wind farm only the visible elements of the infrastructure, i.e. those protruding above the water table, are removed, the impact on hydrological parameters is not expected to change compared to the operation stage of the wind farm. In the event of the removal of underwater facilities, the hydrological parameters will return to the baseline, i.e. before the construction of the farm.

The impact of foundations left in the seabed during the decommissioning stage on hydrological conditions manifests itself primarily in the modification of the flow field of sea currents, as detailed in section 9.1.10 of this section.

No measures are expected to minimize this impact.

Changes in the regime of sea currents at the decommissioning stage of the farm are direct, negative impacts of local extent, permanent, long-term, reversible, of medium intensity.

An assessment of the significance of this impact to the NIS, which was evaluated in the 2015 Report, is presented in Table 44, below.

Table 45. Impact assessment involving regime shift of ocean currents (decommissioning phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Marine waters	Medium	Very low (negligible)	Possible leaving the foundations of the wind farm after its decommissioning will affect the regime of sea currents in the area of the project	Negligible (scale of exposure - local, duration - long-term, intensity - low)	Negligible (magnitude of impact - insignificant, importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

The variant that is the subject of this Report will construct about 70% fewer foundations than envisioned for the furthest-reaching scenario that forms the basis of the assessment in the 2015 Report - NIS 2015, and twice as many as specified in the Environmental Decision, and the use of gravity foundations under the power plants has been ruled out, which also entails correspondingly less occupation of the bottom surface in case the foundations or parts of them have to be left in the bottom during decommissioning. It is therefore considered that the Project will cause lesser impacts from both the Project in the parameters constituting the 2015 NIS and the variant approved in the Environmental Decision.

Thus, it should be considered that both the nature of the impacts does not change and their scope and intensity are smaller than in the case of the variant approved by the Environmental Decision, and thus the proposed change in the parameters of implementation and operation of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.3.9. Wave attenuation wind

As mentioned earlier, impacts on hydrological conditions at the decommissioning stage will only occur if the structural elements of the farm are left in the water.

The impact of wind turbine foundations left in the water on hydrological conditions may manifest itself, among other things, in the attenuation of wind waves, as detailed in section 9.1.11 of this section. The impact itself after the decommissioning of the farm will be no different from the impact during the operation stage.

During the decommissioning phase, no measures are expected to minimize this impact.

Wave attenuation at the decommissioning stage of the farm is a direct, negative impact of local scope, permanent, long-term, reversible, low intensity.

An assessment of the significance of this impact to the NIS, which was evaluated in the 2015 Report, is shown in Table 45, below.

Table 46. Impact assessment involving surface wave attenuation (decommissioning phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Marine waters	Medium	Very low (negligible)	Possible remaining foundations of the wind farm after its decommissioning will have an impact on the surface wave in the area of the project	Negligible (scale of exposure - local, duration - long-term, intensity - low)	Negligible (magnitude of impact - insignificant, importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

The variant that is the subject of this Report will build about 70% fewer foundations than envisioned for the furthest-reaching scenario that forms the basis of the assessment in the 2015 Report - the 2015 NIS - and twice as many as specified in the Environmental Decision, and the use of gravity foundations under the power plants has been ruled out, so its impact on wave action will be proportionately reduced if the foundation structures are left in the water. It is therefore considered that the Project will cause lesser impacts from both the Project in the parameters constituting the 2015 NIS and the variant approved in the Environmental Decision.

Thus, it should be considered that both the nature of the impacts does not change and their scope and intensity are smaller than in the case of the variant approved by the Environmental Decision, and thus the proposed change in the parameters of implementation and operation of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.3.10. An increase in the amount of suspended solids in the water

During the decommissioning stage, more power plant foundations and other farm facilities will be removed from the seabed (unless a decision is made to leave them in the seabed). This will cause stirring of bottom sediments and temporary floating of suspended solids in the water depths. The level of impact will be similar to that during the construction phase, described in detail in section 9.1.12 of this section.

The increase in suspended solids in water at the decommissioning stage of the farm is a direct negative impact of local extent, medium-term (during the decommissioning period), reversible, repeatable during the decommissioning period, with high intensity.

An assessment of the significance of this impact to the NIS, which was evaluated as part of the 2015 Report, is presented in Table 46, below.

Table 47. Impact assessment involving increase in suspended solids in water (decommissioning phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Marine waters	Medium	Very low (negligible)	Removal of wind farm foundations and cables will	Small (scale of exposure - local, duration - short-	Small (magnitude of impact - low,

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
			cause water turbidity in the project area	term, intensity - very high)	importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

The variant that is the subject of this Report will build about 70% fewer foundations than envisioned for the farthest-reaching scenario that forms the basis of the assessment in the 2015 Report - NIS 2015, and twice as many as specified in the Environmental Decision, and the use of gravity foundations under the power plants has been ruled out, so the level of potential water turbidity will decrease proportionally. It is therefore considered that the Project will cause lesser impacts from both the Project in the parameters constituting the 2015 NIS and the variant approved in the Environmental Decision.

Thus, it should be considered that both the nature of the impacts does not change and their scope and intensity are smaller than in the case of the variant approved by the Environmental Decision, and thus the proposed change in the parameters of implementation and operation of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.3.11. Impacts cumulative

Assumptions for the analyses of cumulative impacts of the BIII OWF as it will be implemented after the amendment of the Environmental Decision and other projects on the environment are presented in Section 3.2. On the other hand, a broad description regarding this issue is provided in Section 13 of Volume II of the EIA report.

The 2015 Report, which formed the basis for the impact assessment for the Project in the parameters approved in the Environmental Decision, analyzed the possibility of cumulative impacts in the most far-reaching scenario - NIS 2015, in which all built power plants will be decommissioned at the same time (i.e., depending on the scenario and obtaining additional connection conditions), e.g., as a result of legal changes that make their operation completely unprofitable. In this case, a maximum of a total of 415 power plants with infrastructure will be decommissioned, 110% more than in the assessed NIS 2015. Nonetheless, it was concluded that the impact assessment remains unchanged and does not differ from the assessment for the 2015 NIS and the variant approved in the Environmental Decision.

Impacts during decommissioning will be broadly similar to those during the construction phase. Potential accumulation may be associated with the disturbance of bottom sediments, but the level of accumulation has been assessed as minimal or low. If the foundations are left in the seabed, the impacts will differ little from those during the operational stage.

If the foundations are left in the bottom, the seabed occupation will also remain unchanged from the operational period.

The variant that is the subject of this Report will build about 70% fewer power plants than envisioned for the furthest-reaching scenario that forms the basis of the assessment in the 2015 Report - the 2015 NIS - and twice as many as specified in the Environmental Decision, and the use of gravity foundations under the power plants has been excluded, so that even in the case of cumulative impacts with those associated with the simultaneous decommissioning of other power plants, the total impacts will be less than those assessed in the 2015 Report. It is therefore considered that the Project will contribute less

to cumulative impacts, both from the Project in the parameters constituting the 2015 NIS and from the variant approved in the Environmental Decision.

Thus, it should be considered that both the nature of the impacts does not change and their scope and intensity are smaller than in the case of the variant approved by the Environmental Decision, and thus the proposed change in the parameters of implementation and operation of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

10. Impacts related

Related impacts are understood as a chain of all impacts that may occur in the ecosystem, following the occurrence of an impact on one of its elements. The purpose of assessing associated impacts is to verify that direct impacts on one receptor will not become a source of indirect impacts on another receptor or on the ecosystem as a functional whole, especially in conjunction with direct impacts on that receptor.

A direct impact on one element of the abiotic environment in the study area will usually result in an indirect impact on another abiotic element, and then also on biotic elements. Section 7 of Volume II of the Report presents a matrix of interrelationships, arranged by emission source - emission - impact - direct impact receptor - indirect impact receptor. Associated impacts during the construction phase will be particularly significant.

Impacts in the form of seabed disturbance, particularly the outermost layer of bottom sediments, may cause the following indirect impacts:

- washing out or picking up mineral deposits (especially sands) when preparing the bottom for foundations;
- backfilling mineral deposits with dredged material from bottom dredging for gravity foundations;
- destruction and alteration of habitats, especially benthic habitats;
- reduction in benthic populations, which in turn will reduce the feeding base of fish and birds;
- damage to historic objects on the bottom (provided that other objects are discovered, in addition to the wreck already identified at the stage of environmental studies, which will be protected before the start of work by designating a protection zone).

One of the effects of bottom sediment disturbance will be an increase in the concentration of suspended solids in the water, especially in areas P2, P4 and P5. He, in turn, will cause:

- temporary reduction in transparency (water turbidity);
- change the living conditions for all aquatic organisms, especially for benthos and fish in the juvenile stages of development;
- Another consequence of the agitation of bottom sediments will be the release of pollutants and nutrients from them, and as a result:
- an increase in the amount of pollutants and nutrients in the water;
- changing habitat conditions for aquatic organisms;

- a decrease in the population of pollution-sensitive organisms;
- an increase in plant biomass due to the increased amount of available nitrogen and phosphorus compounds in the water;
- an increase in the concentration of contaminants in the bodies of fish from consuming species.

As a result of the construction work, foundation structures will be placed on the seabed. They, in turn, will have a long-term impact:

- sea currents and wave action in the project area;
- living organisms, by creating an artificial reef and creating favorable conditions for their development;
- navigation and navigation, by creating a navigation exclusion zone in the area of the farm;
- the maritime industry, which will gain from orders of foundations or cables.

Associated impacts at the stage of eventual decommissioning of the farm will be similar to those at the stage of construction. No impacts associated with seabed disturbance are expected on tourism and recreational activities.

A detailed assessment of the associated impacts on the biotic environment, resulting from impacts on the abiotic environment, has been made in the relevant subsequent sections of Volume IV of the Report.

11. Impacts unplanned

Potential unplanned events that may be a source of negative impacts on abiotic and biotic elements of the environment are described in Section 12 of Volume II of the Report.

This chapter assesses the impact of the effects of unplanned events (identified in Section 12 of Volume II of the EIA) on various elements of the abiotic environment, such as:

- pollution of water depths and bottom sediments with petroleum substances (during normal ship operations);
- contamination of the water tone and bottom sediments with petroleum substances (in an emergency);
- contamination of water bodies and bottom sediments with accidentally released municipal waste or domestic sewage;
- contamination of the water tone and bottom sediments with accidentally released chemicals and waste from the construction, operation or decommissioning of the farm;
- contamination of the water tone and bottom sediments with antifouling agents;
- disruption of sediment structure, sediment agitation, secondary sedimentation on the bottom and increased suspended solids associated with unexploded conventional weapons (UXO) explosions.

11.1. Pollution of water depths and bottom sediments with petroleum substances (during

normal operation of ships)

During normal ship operation, spills of various types of petroleum substances (lubricating and diesel oils, gasoline) can occur.

They may contribute slightly to the deterioration of water quality. Heavier oil fractions can be sorbed on the surface of organic and mineral suspensions, which will cause their specific gravity to increase and gradually sink to the bottom. There they can be bound by bottom sediments. However, due to the nature of the sediments in the BIII offshore wind farm area (small amount of organic matter and low content of fine fractions), they will not cause any noticeable deterioration in their quality. It should be assumed that these spills will be small (stage I), up to 20^{m3}. Visible traces of such contamination under favorable conditions can disappear spontaneously due to evaporation and dispersion in the water. The size of these spills will be practically limited to the OWF area. The sensitivity of seawater and bottom sediments to small oil spills from normal ship operations was determined to be low.

The contamination of sediments with petroleum substances is independent of the type of foundation used. It will be more noticeable in areas with fine-grained sediments, which have a greater capacity to absorb petroleum substances.

As a primary minimization measure, it is recommended that vessels be supplied with means to deal with minor oil spills. Mitigation measures are described in more detail in Section 12 of Volume II of the Report.

Pollution of seawater and/or bottom sediments with petroleum substances released during normal ship operations is a direct, negative impact of local scope, temporary or short-term, reversible, repeatable, low intensity during the construction phase.

An assessment of the significance of this impact for the most far-reaching scenario (NIS 2015), which was assessed in the 2015 Report, is presented in Table 47, below.

Table 48. Impact assessment involving contamination of seawater and/or bottom sediments with petroleum substances during normal ship operations (any stage, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Marine waters	Medium	Low	During the normal operation of the ships at each stage of the project, small spills of oil substances may occur	Negligible (scale of exposure - local, duration - temporary or short-term, intensity - low)	Negligible (magnitude of impact - insignificant, importance of the resource - medium)
Seabed / bottom sediments	Large (areas P1 and P3)				Small (magnitude of impact - insignificant, importance of the resource - high)
	Medium (areas P2, P4 and Negligible P5)				Negligible (magnitude of impact - insignificant, importance of

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
					the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

The variant that is the subject of this Report will build about 70% fewer foundations than envisioned for the furthest-reaching scenario that forms the basis of the assessment in the 2015 Report - NIS 2015, and twice as many as specified in the Environmental Decision, and the use of gravity foundations under the power plants has been ruled out, involving the use of a correspondingly smaller number of vessels for project implementation, operation or decommissioning. It is therefore considered that the Project will cause lesser impacts from both the Project in the parameters constituting the 2015 NIS and the variant approved in the Environmental Decision.

Thus, it should be considered that both the nature of the impacts does not change and their scope and intensity are smaller than in the case of the variant approved by the Environmental Decision, and thus the proposed change in the parameters of implementation and operation of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

11.2. Pollution of water bodies and bottom sediments with petroleum substances (in an emergency situation)

During the construction, operation or decommissioning of the farm, leakage of petroleum substances may occur, resulting in pollution of the water table and bottom sediments. A spill can occur as a result of a shipwreck or collision, a construction disaster at one of the farm's facilities, or during maintenance work. In the event of a collision or collision between ships, a Grade III spill can be expected, i.e. more than 50^{m3} (Pawelec et al., 2014).

The visible result of an oil spill is the formation of an oil stain, which, under the influence of gravity and surface tension, spreads at a speed that depends on the type of oil and external conditions. The influence of factors such as oil volume, density, viscosity, temperature, wind speed and time determine the size of the spill. The estimated speed of movement of the oil patch in large bodies of water is about 2 - 3% of the wind speed. It was found that a spill of 1.6 t (1.8^{m3}) of oil in one day of spreading over an area of 1 ^{km2} results in a film thickness of 2µm and a dark color. In contrast, 40 kg of oil results in a spill over an area of 1 ^{km2} with a film thickness of 0.05 µm.

The oil film formed on the surface of the water can cause:

- impeded gas exchange, especially oxygen, between water and the atmosphere;
- a 5 - 10% decrease in light intensity below the water surface (mainly due to the presence of heavy oil and sulfur fractions) limiting photosynthesis;
- increase in water temperature during the day due to absorption of light rays by the oil layer.

At the same time as the spread of the oil slick, other degradation processes run, aiming to reduce the concentration of hydrocarbons on the water surface (e.g., the release of low molecular weight hydrocarbons). Heavier oil fractions, on the other hand, can sorb on the surface of organic and mineral suspensions, which can cause their specific gravity to increase and gradually sink to the bottom. Thus, heavier oil fractions can be bound by bottom sediments, causing contamination. The susceptibility of bottom sediments to contamination depends on the grain size of the sediment and its packing. Loose

sandy sediments and fine silty clay sediments (areas P2, P4, P5) are more susceptible to contaminant absorption. Compact clay sediments inhibit the penetration of contaminants deep into the sediment (areas P1, P3). For these reasons, it was estimated that the intensity of this impact on the seabed would be low in P1 and P3 areas, and medium or high in the remaining areas.

The likelihood of a shipwreck or collision in the Baltic Sea is low. Approximately 2,000 ships (including 200 tankers with oil and other liquids) sail on Baltic waters daily, the number of collisions and accidents in recent years has remained more or less constant (with a slight increase marked) at about 120-140 marine accidents each year. However, most accidents in the Baltic do not cause significant pollution. The number of incidents of pollutants entering the sinkhole remains at about 10-11 per year. However, it should not be forgotten that even just one large-scale accident can seriously threaten the marine environment. The two most serious accidents in the Baltic Sea area since 2001 occurred with the "Baltic Carrier" in 2001 (2,700 tons of oil spilled) and the "Fu ShanHai" in 2003 (1,200 tons of oil spilled). In 2012, 149 ship accidents occurred in the Baltic Sea, 10 of which resulted in pollution. None of the accidents that resulted in water pollution occurred in the area of the Polish economic zone (HELCOM, 2014).

If, on the other hand, one takes into account cases during which more than 5,000 tons of oil pollution would be released into the environment (e.g., an unsealing of a tanker's cargo), the risk of such a situation occurring in the entire Baltic Sea area was estimated (according to data from the BRISK project) at 1 case per 26 years. For the area of the southeastern Baltic, which may include the analyzed area of the BSIII OWF, the risk of such a collision was estimated at 1 case per 1060 years, with the areas of the Wolin Island and Rügen Island, as well as the Hel Peninsula indicated as the most vulnerable areas (www.brisk.helcom.fi; Pawelec et al., 2014a).

During investment works, vessels develop low speeds and in this situation the risk of damage to the fuel tank is very low. Generally, a ship has fuel in several tanks, which reduces the risk of a large spill in the event of a collision. The vessels used for investment work in the construction of wind power plants can have fuel tanks with a total capacity of about 1,200^{m3}. Assuming the failure or collision of the largest units used during the construction, operation or decommissioning stages of the BIII OWF (during inspections, servicing and sudden emergency repairs) and the destruction of the largest tanks, a maximum of (in the worst-case scenario) about 200^{m3} of diesel fuel, 15^{m3} of machine oil and about 2.5 m3^{of} hydraulic oil may leak from one unit (Pawelec et al., 2014; Veldhuizen et al., 2014).

In the event of a construction disaster at the farm (a tower capsizing, or a ship colliding with a tower or substation), a spill of diesel fuel (up to 100^{m3}), machine oil (up to 15^{m3}), hydraulic oil (up to 2.5^{m3}) or transformer oil (up to^{m3}) may occur.

During maintenance of wind turbine components, leakage of various types of oil-based substances can occur, which are replaced during maintenance activities of wind turbines and substations. Transformers will be equipped with devices to minimize such risks. They have sealed oil pans and storm drains will be equipped with an oil separator (Stryjecki et al., 2011; Pawelec, 2014). For this reason, the spill is not expected to spread significantly outside the facility (Pawelec et al., 2014).

The significance of the impact, due to the randomness and sporadic nature of failures and collisions, was assessed as low.

As a minimizing measure, it is recommended that vessels be supplied with means to deal with oil spills. Mitigation measures are described in more detail in Section 12 of Volume II of the Report.

In addition, plans have been developed for the BIII OWF to counteract risks and pollution during construction, operation and decommissioning of the farm. These plans identify the potential area of the basin at risk for various accident and disaster scenarios, as well as specifying methods for counteracting and eliminating oil spills (Pawelec et al., 2014). It should be emphasized that these are preliminary

studies, based on the state of knowledge that is available at the current stage of the project. These plans will be updated, particularly at the construction project stage.

Pollution of the water body or bottom sediments with petroleum substances released in an emergency is a direct, negative impact that is regional in scope, short-term, reversible, repetitive, of low to high intensity (depending on the location).

An assessment of the significance of this impact for the 2015 NIS, which was evaluated in the 2015 Report, is shown in Table 48, below.

Table 49. Impact assessment involving contamination of seawater and bottom sediments with petroleum substances in an emergency (any stage, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Marine waters	Medium	High	In emergency situations, contamination of water depths and bottom sediments with oil-based substances may occur	Small (scale of exposure - regional, duration - short-term, intensity - high)	Small (magnitude of impact - low, importance of the resource - medium)
Seabed / bottom sediments	Large (areas P1 and P3)	Low		Negligible (scale of exposure - regional, duration - short-term, intensity - low)	Small (magnitude of impact - negligible, importance of the resource - high)
	Medium (areas P2, P4 and P5)	Average		Small (scale of exposure - regional, duration - short-term, intensity - high)	Small (magnitude of impact - low, importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

The variant that is the subject of this Report will build about 70% fewer foundations than envisioned for the furthest-reaching scenario that forms the basis of the assessment in the 2015 Report - the 2015 NIS - and twice as many as specified in the Environmental Decision, and the use of gravity foundations under the power plants has been ruled out, involving the use of a correspondingly smaller number of vessels for construction, operation and decommissioning of the project, thereby reducing the likelihood of spills proportionally. It is therefore considered that the Project will cause lesser impacts from both the Project in the parameters constituting the 2015 NIS and the variant approved in the Environmental Decision.

Thus, it should be considered that both the nature of the impacts does not change and their scope and intensity are smaller than in the case of the variant approved by the Environmental Decision, and thus the proposed change in the parameters of implementation and operation of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

11.3. Contamination of water bodies and bottom sediments with accidentally released municipal waste or domestic sewage

During the construction, operation or decommissioning of the wind farm, waste, mainly municipal and other waste not directly related to the construction process, as well as domestic sewage, will be

generated on the vessels, as well as at the construction facilities located on land (at the port serving the investment). Their expected types and quantities, as well as how they will be handled, are presented in Section 10 of Volume II of the Report. Waste and wastewater can be accidentally released into the sea when picked up from ships by another vessel and in the event of an accident, causing a local increase in nutrient concentrations and deterioration of water and sediment quality. However, the pollutants should quickly disperse, so they will not contribute to permanent deterioration of the environment in the project area. The sensitivity of marine waters and bottom sediments to this type of impact is assessed as low.

As a minimizing measure, it is recommended to create procedures related to waste and wastewater handling.

Contamination of water and/or bottom sediments with municipal waste or domestic sewage is a direct, negative impact of local extent, temporary or short-term, reversible, repetitive, low intensity.

An assessment of the significance of this impact for the most far-reaching scenario, which was evaluated as part of the 2015 Report, is presented in Table 49, below.

Table 50. Impact assessment involving contamination of seawater and bottom sediments with municipal waste or domestic sewage (any stage, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Marine waters	Medium	Low	During any stage of the project, there may be an accidental release of municipal waste or domestic sewage into the sea	Negligible (scale of exposure - local, duration - temporary or short-term, intensity - low)	Negligible (magnitude of impact - insignificant, importance of the resource - medium)
Seabed / bottom sediments	Large (areas P1 and P3)				Small (magnitude of impact - insignificant, importance of the resource - high)
	Medium (areas P1 and P3)				Negligible (magnitude of impact - insignificant, importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

The variant that is the subject of this Report will construct about 70% fewer foundations than envisioned for the furthest-reaching scenario that forms the basis of the assessment in the 2015 Report - the 2015 NIS - and twice as many as specified in the Environmental Decision, and the use of gravity foundations under the power plants has been ruled out, involving the use of a correspondingly smaller number of vessels for project implementation, operation or decommissioning, thereby reducing proportionately the possibility of releasing municipal waste or domestic sewage into the water. It is therefore considered that the Project will cause lesser impacts from both the Project in the parameters constituting the 2015 NIS and the variant approved in the Environmental Decision.

Thus, it should be considered that both the nature of the impacts does not change and their scope and intensity are smaller than in the case of the variant approved by the Environmental Decision, and thus the proposed change in the parameters of implementation and operation of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

11.4. Contamination of water bodies and bottom sediments with accidentally released chemicals and waste from the construction, operation or decommissioning of the farm

During the construction of the wind farm, waste directly related to the construction process will be generated on vessels, at the construction facilities located onshore (at the port serving the project) and at the project site. These can include damaged parts of the farm's assembled components, cement, grout, mortar, binders used to join the foundation and power plant components, and other chemicals used during construction work. They can be accidentally released into the sea.

The bulk cement is packed in bags of about 1^{m3}. It was assumed that about $5^{m3\ of}$ product could sink during handling. Grouts, mortars and other binders often contain hazardous substances. E.g., epoxy (two-component) grouts contain in various proportions: epoxy resin, alkyl glycidyl ethers, polyamines. Once they enter the water depths, due to their high density of about 1.3 $^{g\text{-}cm\text{-}1}$, they sink and are deposited on the bottom. These substances are considered a serious threat because they cannot be easily removed from the bottom and are toxic to marine organisms. The scale and estimated probability of their release were estimated in the Plan for Counteracting Risks and Pollution during Construction and Decommissioning of the Offshore Wind Farm "OWF Central Baltic III" (Pawelec et al., 2014).

During the operation of the farm, maintenance of its facilities will be carried out. Accidental release of small amounts of waste or operating fluids into the sea cannot be ruled out.

During decommissioning of the farm, it seems inevitable that bottom sediments will be contaminated with waste from the process. The magnitude of this impact will depend on the method adopted for carrying out this work (cf. description of the decommissioning stage), and the greatest contamination may occur if gravity foundations have to be crushed.

The anticipated types and quantities of waste are presented in Section 10 of Volume II of the Report.

For this type of investment like an OWF, a detailed plan is generally developed to deal with risks and pollution arising during construction, operation and decommissioning, which develops minimization measures and how to deal with such events. It is recommended that such procedures be created as a minimization measure.

Contamination of water and/or bottom sediments with chemicals or wastes associated with the process of construction, operation or decommissioning of the farm is a direct, negative impact of local extent, medium-term, irreversible, repetitive, of medium intensity.

An assessment of the significance of this impact to the NIS, which was evaluated in the 2015 Report, is shown in Table 50, below.

Table 51. Impact assessment involving contamination of seawater and bottom sediments with waste associated with the construction process or operational fluids (any stage, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Marine waters	Medium	Average	During the construction or decommissioning of the farm, there may be an accidental release into the sea of waste associated with the process, and at any stage of the project there may be an accidental release of operating fluids	Insignificant (scale of exposure - local, duration - medium-term, intensity - medium)	Negligible (magnitude of impact - insignificant, importance of the resource - medium)
Seabed / bottom sediments	Large (areas P1 and P3)				Small (magnitude of impact - insignificant, importance of the resource - high)
	Medium (areas P2, P4 and P5)				Negligible (magnitude of impact - insignificant, importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

The variant that is the subject of this Report will build about 70% fewer foundations than envisioned for the furthest-reaching scenario that forms the basis of the assessment in the 2015 Report - NIS 2015, and twice as many as specified in the Environmental Decision, and it excludes the use of gravity foundations under the power plants, so the possibility of releasing waste or chemicals into the water during the construction, operation or decommissioning of the farm will be proportionately reduced. It is therefore considered that the Project will cause lesser impacts from both the Project in the parameters constituting the 2015 NIS and the variant approved in the Environmental Decision.

Thus, it should be considered that both the nature of the impacts does not change and their scope and intensity are smaller than in the case of the variant approved by the Environmental Decision, and thus the proposed change in the parameters of implementation and operation of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

11.5. Contamination of water depths and bottom sediments with agents antifouling

To protect the hulls of ships from overgrowth, biocides are used, which may include, for example, copper compounds, mercury compounds, organotin compounds (such as tributyltin - TBT). These substances can pass into the water's depths and eventually be retained in the sediment. It should be assumed that the emission of these compounds will be limited by dilution in the water depths. Of the substances listed, organotin compounds are the most harmful (toxic) to aquatic organisms. TBT (the most harmful substance) is currently banned in antifouling paints, but the presence of these compounds

in older units cannot be ruled out. The sensitivity of seawater and bottom sediments to biocides released from hulls was determined to be medium.

As a minimizing measure, it is recommended that vessels whose hulls have not been coated with TBT-containing antifouling paint be used at any stage of the project. This will eliminate this most harmful impact on aquatic organisms.

Contamination of water and/or bottom sediments with antifouling substances is a direct, negative impact of local or regional extent, short-term, reversible, repeatable, low intensity during the construction phase.

An assessment of the significance of this impact for the 2015 NIS, which was evaluated as part of the 2015 Report, is presented in Table 51, below.

Table 52. Impact assessment involving contamination of seawater and/or bottom sediments with antifouling substances (any stage, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Marine waters	Medium	Average	The release of antifouling substances may occur during normal ship operations	Negligible (scale of exposure - local or regional, duration - short-term, intensity - low)	Negligible (magnitude of impact - insignificant, importance of the resource - medium)
Seabed / bottom sediments	Large (areas P1 and P3)				Small (magnitude of impact - insignificant, importance of the resource - high)
	Medium (areas P2, P4 and P5)				Negligible (magnitude of impact - insignificant, importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

The variant that is the subject of this Report will construct about 70% fewer foundations than envisioned for the furthest-reaching scenario that forms the basis of the assessment in the 2015 Report - the 2015 NIS - and twice as many as specified in the Environmental Decision, and the use of gravity foundations under the power plants has been ruled out, which entails the use of a correspondingly smaller number of vessels to implement, operate or decommission the project, thereby reducing proportionally the possibility of releasing antifouling substances. It is therefore considered that the Project will cause lesser impacts from both the Project in the parameters constituting the 2015 NIS and the variant approved in the Environmental Decision.

Thus, it should be considered that both the nature of the impacts does not change and their scope and intensity are smaller than in the case of the variant approved by the Environmental Decision, and thus the proposed change in the parameters of implementation and operation of the Project does not affect

the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

11.6. Disruption of sediment structure, sediment agitation, secondary sedimentation on the bottom and increase in suspended solids associated with UXO explosions

If UXO detonation is carried out, it is possible to disrupt the structure of bottom sediments, agitate and redeposit them, and increase suspended solids in the water.

In the case analyzed, impacts are expected to be analogous to those from physical interference with the bottom during the construction phase (see Chapter 9.1 of this section).

As a direct result of the disturbance of the bottom sediment structure, suspended solids will rise and dissipate (resuspension) in the water depths, potentially releasing pollutants and nutrients into the water, re-depositing on the bottom. Some heavy metals, pollutants and nutrients may be released from the bottom sediments as a result of the agitation, analogous to the construction phase. In this case, there may be a deterioration of water quality due to an increase in the concentration of harmful and biogenic substances (due to the passage from the sediment to the water body as a result of sediment uplift processes). These sediments will also promote the formation of more suspended solids, which will persist in the water depths for a long time. Intense resuspension can cause the release of nutrients immobilized in the sediment and contribute to eutrophication. In the case of sandy sediments with low organic matter content (e.g., coarse-grained sandy sediments), the processes described will be less intense. These sludges are generally characterized by small amounts of fine fractions and low concentrations of metals and persistent organic pollutants.

It is also assumed that there may be temporary turbidity in the water due to an increase in suspended solids in the water. Aggradation of bottom sediments can also affect potential mineral accumulations.

It is estimated that the scale and extent of impacts associated with a possible detonation will vary depending on the size of the detonated charge and the type and volume of agitated sediments, but will not exceed the regional scale. These will be high-intensity impacts.

The following is an assessment of the impact on the abiotic environment due to the decommissioning of UXO.

Table 53. Impact assessment of disruption of bottom sediment structure due to UXO detonation (any stage)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Seabed/bottom sediments	Large (areas P1 and P3)	Low (areas P1 and P3)	Due to the detonation of UXO, the structure of the bottom sediments will be disturbed	Negligible (scale of exposure - local, duration - short term, intensity - high)	Small (magnitude of impact - insignificant, importance of the resource - medium/large)
	Medium (areas P2, P4 and P5)	Medium (areas P2 and P4) or high (area P5)			

Table 54. Impact assessment involving the release of contaminants and nutrients from the sediment into the benthic water table as a result of UXO detonation (any stage)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Seabed/bottom sediments	Large (areas P1 and P3)	Low (areas P1 and P3)	Due to the detonation of UXO, there will be a release of contaminants and nutrients from the sediment into the water body	Negligible (scale of exposure - regional, duration - short-term, intensity - high)	Small (magnitude of impact - insignificant, importance of the resource - high)
	Medium (areas P2, P4 and P5)	Medium (areas P2 and P4) or high (area P5)		Small (scale of exposure - regional, duration - short-term, intensity - high)	Small (magnitude of impact-small, importance of resource-medium)
Marine waters	Medium	Average		Small (scale of exposure - regional, duration - short-term, intensity - high)	Small (magnitude of impact - low, importance of the resource - medium)

Table 55. Assessment of the impact involving the disruption of the bottom structure as a result of UXO detonation (any stage)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Seabed/bottom sediments	Large (areas P1 and P3)	High	Due to the detonation of UXO, there will be violations of the bottom structure	Moderate (scale of exposure - local, duration - long-term, intensity - high)	Moderate (magnitude of impact - moderate, importance of the resource - high)
	Medium (areas P2, P4 and P5)	Average		Small (scale of exposure - local, duration - long-term, intensity - high)	Small (magnitude of impact - moderate, importance of the resource - medium)

Table 56. Assessment of the impact involving the change in bottom morphology as a result of UXO detonation (any stage)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Seabed / bottom sediments	Large (areas P1 and P3)	Low (areas P1 and P3)	Due to the detonation of UXO, there will be a change in	Moderate (scale of exposure - local, duration - long-	Moderate (magnitude of impact - moderate,

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
			bottom morphology	term, intensity - high)	importance of the resource - high)
	Medium (areas P2, P4 and P5)	Medium (areas P2 and P4) or high (area P5)		Small (scale of exposure - local, duration - medium-term, intensity - high)	Small (magnitude of impact - low, importance of the resource - medium)

Table 57. Assessment of impacts involving leaching, selection or burial of mineral accumulations as a result of UXO detonation (any stage)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Gravelly sand deposits	Medium	High	Due to the detonation of UXO, there will be a change in mineral accumulations	Small (scale of exposure - local, duration - short-term, intensity - very high)	Small (magnitude of impact - low, importance of the resource - medium)

Table 58. Impact assessment of the increase of suspended solids in water due to detonation of UXO (any stage)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Marine waters	Medium	Very low (negligible)	Due to the detonation of UXO, there will be water turbidity at the detonation site	Small (scale of exposure - local, duration - short-term, intensity - very high)	Small (magnitude of impact - low, importance of the resource - medium)

The 2015 report did not include an assessment of unplanned impacts associated with UXO detonation. The assessment carried out in this report showed low magnitude and significance of the impact. At the same time, it should be emphasized that the proposed modifications to the Project do not affect the Project's impacts in relation to the Project in the parameters approved by the Environmental Decision. The possibility of such an impact is related to the area of the seabed covered by the works during the course of the Project, and this will remain unchanged both after the implementation of the proposed modifications to the Project.

11.7. Cumulative impacts in emergency situations emergencies

The only unplanned impact that may be cumulative will be contamination of the water tone and bottom sediments with petroleum substances.

During the preparation of the 2015 Report, it was found that even assuming that the number of vessels in the construction / operation / decommissioning stages doubles compared to the most far-reaching scenario (i.e., a maximum of 400 power plants will be operated), the assessment will remain unchanged, as shown in the table below.

Table 59. Assessment of cumulative impacts involving contamination of seawater and bottom sediments with petroleum substances (unplanned impacts, any phase, NIS 2015)

Impact	Seabed and bottom sediments	Marine waters	Mineral deposits	
			Gravelly sands	Hydrocarbons
Pollution of water bodies and bottom sediments with petroleum substances (emergency situations)	Small	Small	-	-
Pollution of the water tone and bottom sediments with petroleum substances (normal operation)	Negligible / Small*	Skip		

* depending on the bottom structure

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

The variant that is the subject of this Report will build about 70% fewer turbines, and thus foundations, than envisioned for the furthest-reaching scenario that forms the basis of the assessment in the 2015 Report - the 2015 NIS - and twice as many as specified in the Environmental Decision, which entails less vessel traffic at each stage, and thus less likelihood of accidents and the cumulative effects of them, if any. It is therefore considered that the Project will cause lesser impacts from both the Project in the parameters constituting the 2015 NIS and the variant approved in the Environmental Decision.

Thus, it should be considered that both the nature of the impacts does not change and their scope and intensity are smaller than in the case of the variant approved by the Environmental Decision, and thus the proposed change in the parameters of implementation and operation of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

12. Assessment of the impact on the integrity, coherence and object of protection of Natura sites 2000

This chapter analyzes the potential impact of the BII OWF, at each of its stages, on abiotic environmental elements protected under the Natura 2000 network. The assessment was performed in accordance with the methodology described in Section 5 of Volume I of the Report.

12.1. Initial assessment - screening

Pre-assessment is the process by which the project's likely impacts on Natura 2000 sites are identified (either singly or in conjunction with other projects or plans) and an analysis is made of whether the anticipated impacts are likely to have a significant effect on these sites.

After the analysis of the impacts of the BIII OWF, conducted in the 2015 Report, it was concluded that the project's impacts on the abiotic environment will be overwhelmingly limited to the area of the farm.

The only impact that was found to have the potential to significantly extend beyond the farm area was the rise and spread of suspended solids in the water depths and their redeposition to the bottom. This indirect impact is a direct result of the disturbance of the bottom sediment structure during construction activities (and to a lesser extent during operation and decommissioning of the farm). For a detailed description of this impact, see Section 9.1.12 of this section of the Report, above.

As can be seen from the analyses performed, the results of which are presented in Section 4 of Volume II of the Report and Chapter 9 of this section, the sediment stirred up during the farm's construction work will fall, depending on the variant of the project, covering the bottom to an average thickness of 0.2 - to 0.4 mm. The amount of suspended solids carried is so small that it can be compared with the rate of sedimentation in Baltic waters, which ranges from 0.005 to about 0.2 mm/year per year (Gradzinski et al., 1986). The amounts of suspended solids transferred to Natura 2000 sites are therefore unmeasurable from a practical point of view.

Some heavy metals, pollutants and nutrients will be released from the bottom sediments as a result of the agitation, as discussed in section 9.1.2 of this section. There will also be a temporary turbidity of the water. However, these impacts will not result in significant associated impacts on benthic habitats, as well as on birds that are the subject of protection h Natura 2000 areas, as further described and evidenced in sections 3 and 5 of Volume IV of the Report.

Significantly, the variant that is the subject of this Report will build about 70% fewer foundations than envisioned for the furthest-reaching scenario that forms the basis of the assessment in the 2015 Report - NIS 2015, and twice as many as specified in the Environmental Decision, and the use of the most invasive gravity foundations under the power plants has been excluded, limiting the permissible foundation types to monopile and jacket type only, and only for additional infrastructure has the possibility of gravity foundations been retained, but their number has been limited to one. It is associated with a significantly lower extent of all impacts on abiotic elements during construction, operation and decommissioning. Thus, it is considered that if the proposed modifications are implemented, the disturbance that is a source of suspended solids uplift and dissipation in the water body will also be significantly reduced, thereby further reducing the potential for impacts on Natura 2000 sites compared to the Project in the parameters constituting the 2015 NIS, as well as the variant approved in the Environmental Decision.

13. Impacts transboundary

The BIII OWF is not expected to cause transboundary impacts on abiotic elements of the environment lying within the borders of other countries (including their exclusive economic zones).

An analysis of the scale of the proposed farm's impacts on the seabed, bottom sediments, seawater and mineral deposits showed that the impact on these receptors will be almost exclusively local, at most regional (see Chapter 9 of this section of the EIA, above), reaching a maximum of several kilometers from the farm's borders, while the nearest exclusive economic zone of another country (Sweden) is about 52 km away.

There are also no deposits of raw materials of international importance in the area of the planned project. Due to the distance of the BIII OWF from the borders of the Polish EEZ, there is no risk of interference with raw material exploration through the construction of the farm's infrastructure. There are also no exploration techniques for which the impact of the construction of the farm infrastructure would have an impact at distances greater than 20 kilometers.

14. Proposal monitoring

The proposed changes to the terms of the Environmental Decision do not affect the conditions for monitoring specified in the Environmental Decision. The conditions and rules for conducting monitoring, including for abiotic elements of the environment, are specified in the Environmental Decision in section II.2. The subject of this report is also not a change in these conditions.

15. Summary and conclusions

According to the results of the 2015 Report's assessment of the impact of the BIII OWF on the abiotic environment, the planned wind farm will not have a significant negative impact on the seabed (including bottom sediments), marine waters and mineral deposits in the area of the Project either in the variant selected for implementation or in the reasonable alternative variant.

Given the significantly smaller scope of the currently proposed variant of the project, it is even less likely to generate any negative impacts on the abiotic elements of the environment.

It should be borne in mind that the carried out assessment of the impact on abiotic elements of the environment is also the starting point and an important element of the assessment of the impact of OWF BIII on biotic elements, i.e. living organisms, whose functioning depends very much on the quality of sediments and waters. The results of the impact assessment on abiotic elements of the environment, particularly water and sediment, were used in the impact assessments on benthos, fish, mammals and birds, which are included in the following sections of Volume IV of the Report.

It is not expected that there could be any cumulative impacts on the seabed or seawater during the simultaneous operation of several neighboring projects in the area of the farm, since any impacts will be limited to the immediate vicinity of the individual farm facilities.

The wind farm is located in Poland's exclusive economic zone. Impacts on the abiotic environment are local. The BIII OWF is not expected to cause transboundary impacts, i.e. in the maritime areas of neighboring countries.

Unplanned impacts, primarily related to the decommissioning of UXO and vessel accidents and spills, will not significantly affect the abiotic environment. Potential contaminants will largely be dispersed in the water, and the amount of substances that could potentially be released as well as the likelihood of an emergency is low.

The BSIII OWF is located at a distance of about 5.5 km from the nearest Natura 2000 area, the subject of protection of which are abiotic habitats. Due to the local scale of impacts, the possibility of significant negative impacts of the farm on the seabed, bottom sediments and marine waters in Natura 2000 network areas, as well as other protected areas, is not expected.

A summary of the assessment of the impact of the amendments to the Environmental Decision on the results of the assessment of the impact on the abiotic environment of the Project is presented in the following tables.

15.1. Seabed and sediments bottom

Table 60. Assessment of the impact of the Project update on the results of the assessment of the impact of OWF BIII on the seabed and bottom sediments - construction phase

Changes in the regime of sea currents		No	Insignificant	Skip	Reducing the impact
Ripple suppression		No	Insignificant	Skip	Reducing the impact
Increase in suspended solids in water		No	Small	Small	Reducing the impact
Contamination with antifouling substances		Use of vessels whose hulls have not been coated with TBT-containing antifouling paint	Insignificant	Skip	Reducing the impact
Pollution with oil substances during normal operation		Provision of vessels with means for elimination of minor oil spills	Insignificant	Skip	Reducing the impact

15.3. Mineral deposits minerals

Table 66. Assessment of the impact of updating the parameters of the Project on the results of the assessment of the impact of OWF BIII on mineral deposits - construction phase

Impact	Importance of the resource	Minimization measures	Magnitude of impact	The significance of the impact	The impact of updating the parameters of the Project on the significance of the impact
Washing out, shoveling or backfilling of gravel sand deposits	Medium	No	Small	Small	Reducing the impact
Use of sand for foundation construction	Medium	No	Moderate	Small	Reducing the impact
Obstructing access to gravel sand deposits	Medium	No	Moderate	Small	Reducing the impact
Obstructing access to hydrocarbon deposits	Small	No	Insignificant	Skip	Reducing the impact

Table 67. Assessment of the impact of updating the parameters of the Project on the results of the assessment of the impact of OWF BIII on mineral deposits - exploitation stage

Impact	Importance of the resource	Minimization measures	Magnitude of impact	The significance of the impact	The impact of updating the parameters of the Project on the significance of the impact
Washing out or backfilling gravel sand deposits	Medium	No	Insignificant	Skip	Reducing the impact
Obstructing access to gravel sand deposits	Medium	No	Moderate	Small	Reducing the impact
Obstructing access to hydrocarbon deposits	Small	No	Insignificant	Skip	Reducing the impact

Table 68. Impact of updating the parameters of the Project on the results of the assessment of the impact of OWF BIII on mineral deposits - decommissioning stage

Impact	Importance of the resource	Minimization measures	Magnitude of impact	The significance of the impact	The impact of updating the parameters of the Project on the significance of the impact
Washing out or backfilling gravel sand deposits	Medium	No	Small	Small	Reducing the impact

16. Shortcomings in technology and gaps in modern knowledge

The main problem for the contractors of the study and assessment of the impact of OWF BIII on abiotic elements of the environment was the lack of similar investments in Poland to assess the scope and scale of impacts. In this situation, the knowledge and experience of countries where offshore wind energy is developed has been used.

Making a fully objective and reliable assessment of the magnitude of the impact of wind farms on the marine environment, both in relation to the sites of planned locations and within further, adjacent bodies of water, is a very complex issue, and many theoretical, modeling and operational issues related to their impact on the hydrodynamics and hydrophysics of phenomena occurring across the entire section of the depths have not yet been sufficiently recognized. Therefore, the analyses presented and the resulting conclusions for the Polish areas of the South Baltic still require thorough research. Although wind farms of various sizes have been built and operated in the sea areas of neighboring Baltic states (Germany, Sweden, Denmark) for several - more than a dozen years, it is nevertheless difficult to fully adapt the experience and lessons learned from their construction and operation to the realities and requirements of Polish sea areas due to the different specificity of hydrological conditions, the relatively short time of operation at sea and limitations in access to operational information.

Abbreviations and definitions

Bentofag	An animal that feeds mainly on benthos (benthic organisms) (Zmudzinski, 2002)
Environmental Decision	Decision on environmental conditions issued by the Regional Director for Environmental Protection in Gdańsk on July 7, 2016, ref. No. RDOŚ-Gd-WOO.4211.12.2015.KP.22, for the project named "Construction of the Bałtyk Środkowy III Offshore Wind Farm"
Epifauna (Epibentos)	Fauna living on the surface of the bottom (Zmudzinski, 2002)
EEZ	Exclusive Economic Zone (Exclusive Economic Zone)
FEW Baltic II	Baltic II wind farm
Phytophilous fauna	"Herbivorous" animals that live among plants (Zmudzinski, 2002)
IMGW-PIB	Institute of Meteorology and Water Management - National Research Institute
Infauna	A community of organisms living inside bottom sediments (Zmudzinski, 2002)
IPW	Internal connection infrastructure
NPS	National Electricity System
IMF Baltica 2	Baltica 2 offshore wind farm
IMF Baltica 3	Offshore wind farm Baltica 3
IMF BII	Offshore wind farm OWF Baltic II
OWF BIII/ Project	Bałtyk Środkowy III Offshore Wind Farm
MIR-PIB	Marine Fisheries Institute - National Fisheries Institute
MIP	Offshore Transmission Infrastructure
Mytilization	A word derived from English ("mytilization"), the intensive and rapid colonization of hard substrate by the mussel Mytilus trossulus, including the artificial substrate of the underwater part of wind power plants (Krone et al., 2013)
NIS 2015	The most far-reaching scenario from the 2015 Report, which is a set of parameters of the project causing the most far-reaching impacts, and which was the basis for conducting an environmental impact assessment during the proceedings that ended with the issuance of the Environmental Decision.
EIA	Environmental impact assessment
Opportunistic species	Easily adaptable to changing habitat and nutritional conditions, resistant to poor environmental conditions, resulting especially from high levels of environmental pollution (Zmudzinski, 2002)
Vagile organism	Free-living, not permanently attached to the substrate (Zmudzinski, 2002)
POM	Polish maritime areas
PEM	Electromagnetic field
PSZW	Permit for the erection and use of artificial islands, structures and devices in Polish maritime areas
EIA/ EIA Report/	Environmental impact report
Report 2015	The Environmental Impact Assessment Report for the purposes of the procedure finalized by the decision of the Regional Directorate for

	Environmental Protection dated July 7, 2016, ref. No. RDOŚ-Gd-WOO.4211.12.2015.KP.22
ROV	Remotely Operated Vehicle for underwater film inspection (Remotely Operated Vehicle)
Ecological succession	The process of ecosystem evolution, that is, gradual directional changes that lead to a change in the species structure of the ecosystem, that is, the transformation of one ecosystem into another (Zmudzinski, 2002)
Euryhaline taxon	Able to live in a relatively wide range of water salinity, such as in both brackish and brackish waters, and sometimes even in fresh water (Zmudzinski, 2002)
TBT	Tributyltin

1. Summary non-specialist

A non-specialist summary of the results of the assessment of the impact of the update of the conditions for implementation and operation of the Project - OWF BIII, for which the Environmental Decision was issued, on benthos and habitats protected within the Natura 2000 network is included in Section 5.2 of Volume VI of the Report.

2. Introduction

This section of the Report assesses the potential impacts of changing and updating the conditions for implementation and operation of the Project - BIII OWF on benthos and Natura 2000 protected habitats.

Characteristics of the benthos occurring in the area of OWF BIII and in the zone of its potential impacts are presented in Chapter 6 of Volume III of the Report. The assessment of the impact on natural habitats was not presented separately in the 2015 Report, so its current inclusion is also due to changes in the regulations defining the content of the environmental impact report.

Habitats of Community Interest have not been identified in the BIII offshore wind farm area, so the project will not directly affect these habitats, e.g. by physically transforming them. Nevertheless, two types of protected natural habitats - 1110 Sandbanks under the sea and 1170 Rocky and rocky seabed, reefs - are the subject of protection in the Slupsk Shoal PLC990001 Natura 2000 area, located about 5.5 km to the west of the BIII OWF area. Therefore, the characteristics of the habitats in question, as well as the assessment of the impact of OWF BIII on these habitats, are presented in section 12 of this chapter, in the context of the potential impact of the planned project on Natura 2000 sites.

3. Description of the planned project

3.1. Parameters of the project affecting the scale and type impacts

The parameters of the BIII OWF that are relevant to the assessment of the project's impact on benthos are:

- farm location;
- area of the farm - total and buildable;
- foundations - types, number, dimensions, method of foundation and the seabed area occupied by them;
- power cables - their length and the surface of the bottom disturbed during their laying.

With regard to natural habitats, potential impacts on them will be influenced by the parameters of the project that determine the zone of sediment redeposition extent, i.e. primarily the types, number, dimensions of foundations and the bottom area transformed for them (especially the total volume of dredging), as well as the length of power cables and the bottom area disturbed during their laying.

All of the above parameters, for the construction, operation and decommissioning phases of the Project, are presented and characterized in terms of potential emissions and environmental disturbances in Volume II of the Report.

3.2. Projects whose impacts may cumulate with the impacts of OWF BIII on benthos and natural habitats

Information on existing and planned projects whose impacts may cumulate with those of OWF BIII, resulting in their amplification, and the basic assumptions for the analysis of cumulative impacts of the planned farm are presented in Section 13 of Volume II of the Report.

In the area of the BIII OWF, no existing or planned projects for which an environmental decision has been issued that could potentially, together with the BIII OWF, cause cumulative impacts on benthos have been identified, with the exception of the planned project involving the construction of the BIII OWF Offshore Power Transmission Infrastructure (MIP BIII). The project in question has the potential to cause cumulative impacts with OWF BIII on benthos, related to the agitation of bottom sediments during the construction phase. The impact in question is assessed in Section 9.1.5 of this document.

On the other hand, taking into account that within the framework of the assessment of the impact of a project on the Natura 2000 area, the cumulative impact of the project with other executed, executed or planned projects is taken into account, regardless of whether a decision on environmental conditions has been issued for them, the assessment of cumulative impacts with regard to natural habitats protected within the Natura 2000 network (see: Chapter 12 of this document) includes projects that may cause cumulative impacts related to the agitation of bottom sediments at the stage of construction and decommissioning of the OWF BIII within a radius of up to approx. 10 km from its borders, i.e.:

- Baltica 3 offshore wind farm (Baltica 3 offshore wind farm area);
- MIP BIII;
- Baltic Power OWF;
- Aggregate mining on Slupsk Shoal.

4. Existing pressures anthropogenic

The area of the planned project is located at a distance of 23 kilometers from the coastline, along which no major industrial centers, as well as large concentrations of people, are located in the hinterland. The anthropogenic impacts, which include the area of the planned project in the depth range of 20-40 m, include the process of eutrophication or fishing pressure.

Eutrophication, which has been observed in the Baltic Sea since the 1950s, through excessive inputs of nitrogen and phosphorus compounds (from rivers and the atmosphere), partly as a result of economic activity, enriches the environment with nutrients, having a negative impact on the benthos (Andersen and Laamanen, 2009). Under the influence of eutrophication, the same trend is taking place among phytobenthos throughout the Baltic Sea (including POM): a decreasing proportion of perennial kelp and brown algae species (especially Fucus vesiculosus) in favor of fast-growing filamentous brown algae and anoxia-inducing algal mats lying on the bottom (Ciszewski et al, 1992; Kautsky et al, 1992; Kukk, 1995; Kruk-Dowgiałło, 1996; Eriksson et al, 1998). Oxygen deficits in bottom waters, which are unfavorable for macrozoobenthos, can occur as a result of stagnant waters, especially in the deep-water zone of the Baltic Sea, in the absence of inflows from the North Sea, and during cyanobacterial blooms. Most macrozoobenthos species are very sensitive to the growth of organic matter on the bottom and conditions of hypoxia (oxygen concentration < 2 ml O2/l) or anoxia (lack of oxygen, hydrogen sulfide appears) eventually perishing, while others are more tolerant and can survive even a few weeks under unfavorable conditions or undertake an escape from the area under oxygen deficient conditions (Janas

et al. 2004, Andersen and Laamanen 2009, HELCOM Secretariat 2013). In the central Baltic, cyanobacterial blooms have been occurring since 1960, especially in July and August (Rönnberg and Bonsdorf 2004), so late summer may see processes of intense mineralization of organic matter (Janas et al., 2004) leading to oxygen deficits. The more important inflows from the North Sea reaching the bottom waters of the southern Baltic occurred in 1993 and 2003. (Nausch et al., 2003). In 2013, inflows from the North Sea of 100-300 ^{km3} reached the central Baltic, so there was no hypoxic condition. The average minimum oxygen concentration in the bottom layer in the waters of the Central Coast, in the area where OWF BIII is planned to be sited, was 5.55 $^{cm3/dm3}$ in 2012. (Burakowska et al., 2013). In 2012, the status of eutrophication of the marine environment according to the Water Framework Directive in the waters of the area of the planned project was moderate (Figure 19.1., Chapter 19 in Lysiak-Pastuszak et al., 2013). In general, the region of the planned project, due to the possibility of good oxygenation (due to full mixing of the water by storms), has the greatest potential capacity to neutralize the effects of eutrophication, in contrast to the zone below the halocline (Andrulewicz et al. 2008), where long-term oxygen deficits may occur. In the Baltic Proper, the permanent halocline floods at a depth of 60-80 m (Andersen and Laamanen 2009). In addition, the load of pollutants carried into the coastal zone of the southern Baltic from the atmosphere (including nitrates, sulfates and heavy metals) is low (Danowska and Woroń, 2013). HELCOM (2005) shows that atmospheric nitrogen input to the Baltic Sea accounts for only 25% of the total marine nitrogen contribution from anthropogenic sources. In addition, it is necessary to consider the toxicity of POPs (DDT, PCBs, PAHs), which results from their accumulation in bottom sediments and subsequently in the downstream trophic chain of marine organisms (Pempkowiak, 1997). POPs present in sediments can have phytotoxic or stimulatory effects on plant growth and toxic effects on fauna by accumulating, including in the soft tissues of bivalves (Galer et al., 1997). As a result, this can lead to a decline in benthic abundance and biodiversity (Kingston, 1992; Grnat and Briggs, 2002). However, concentrations of POPs in bottom sediments and seawater in the area of OWF BII occurred at low levels and did not exceed values typical of sandy sediments or did not deviate substantially from typical contents for southern Baltic waters (Dembska et al., 2015). The above reasoning shows that the BIII OWF area is not under the direct influence of land-based pollution sources and the degree of anthropogenic pressure that could affect the benthos is insignificant.

Fishing, especially bottom trawling, destroys the seafloor to a sediment depth of 3-6 cm and can also negatively affect the structure, biodiversity and functioning of the benthos (Kaiser and de Groot, 2000; Kaiser et al. 2006). Slow-growing benthic species that reach large sizes are particularly sensitive to the effect of trawling (Kaiser et al., 2000), while low mortality is observed among organisms of small size in the face of the described impact (Gilkinson et al., 1998). The mortality rate of bivalves as a result of bottom fishing is 30-40% (Bergman and van Santbrink, 2000). The recovery of macrofaunal resources (reaching the initial biomass) after the bottom devastation process, even after a single bottom trale, is about 5 years (Dinmore et al., 2003). The share of bottom trawling in the Project area fluctuated between 11% (2017) and 21% (2015) in 2013-2018. Due to the low fishery productivity of the analyzed area, which accounted for 6% of the productivity of the Polish Baltic Sea zone in 2013-2018, the pressure from fishing on the benthos should be considered insignificant.

The BIII offshore wind farm area is located outside the main shipping lane, but in close proximity to it (TSS - about 0.8 km to the south). Seasonally, there is tourist traffic associated with fishing. During the normal operation of ships, spills of various types of substances (diesel and lubricating oils, gasoline, etc.) may enter the water depths in small quantities, causing deterioration of water quality and bottom sediments, which may indirectly affect the benthos.

5. Description of anticipated effects on the environment if the project is not undertaken project

This chapter analyzes three scenarios for the likely impact, or lack thereof, on benthos if the BIII OWF project is not undertaken:

- offshore wind energy will not be developed in Polish maritime areas, so the assessed project, or one similar to it, will not be implemented,
- offshore wind energy will be developed in the Polish maritime areas, but the assessed project - BIII OWF - will not be implemented,
- in Polish maritime areas, investments in offshore wind energy will not be made, but the mining industry will develop.

The results of the analysis are shown in the table below.

Table 1. Effects on benthos if the project is not undertaken

Lp.	Script	Impact on benthos
1.	Offshore wind power will not be developed	No activities related to the construction, operation or decommissioning of offshore wind farms would mean no impact on the benthos, so its assemblages on a short-term scale will remain in their current ecological state. The area designated for OWF BIII will remain unchanged and will continue to be used as before (no change in the structure of the bottom surface, no navigational impediments, a larger fishing area). In the analyzed area, as a result of normal ship operation, spills of various types of substances (diesel and lubricating oils, gasoline, etc.) may enter the water depths in small quantities, causing deterioration of water quality and sediments, and indirectly - the living conditions of benthic organisms. However, the qualitative and quantitative structure of the benthos of this region will be subject to processes occurring in the entire South Baltic seabed zone, in a similar depth range (20 - 40 m). Changes in the qualitative and quantitative parameters of the benthos in the long term are caused by large-scale processes, such as. progressive (or decreasing) eutrophication, increased water warmth as a result of global climate change, the effect of "water sweetening" when water exchange with the North Sea is reduced and at the same time increased river runoff, or "oceanization" as a result of increased saltwater inflow from the North Sea caused by extreme meteorological phenomena - intense and prolonged winds from westerly directions. The direction of possible changes cannot be determined with high probability by scientific methods.
2.	Offshore wind energy will be developed, but OWF BIII will not be realized	In the event that the BIII OWF is not built, but other wind farms are built in neighboring locations as a result of offshore wind energy development, no significant impact on benthos is expected in the BIII OWF area. Only the suspended solids that will rise during the

Lp.	Script	Impact on benthos
		construction of these farms may settle in a small layer on the seabed. From the point of view of impacts on benthos, the type of sediments present at the planned OWF site will be important. A greater impact involving greater redistribution of pollutants deposited in the sediments into the water body and the formation of greater long-lived suspended solids will be observed for clay sediments (with high organic matter and fine fractions), which are generally characterized by higher contents of metals, nutrients and organic pollutants. There will be less impact when offshore wind farms are located in the area of coarse sands (with low organic matter and fine fractions), which are characterized by a low content of metals, nutrients and organic pollutants. The area allocated for OWF BIII will remain unchanged and continue to be used as before.
3.	Offshore wind power will not develop, but mining industry will grow	Potential changes in the benthos of the BIII offshore wind farm area could also result in other uses of marine resources in its immediate vicinity, such as aggregate extraction from the seabed or oil/gas extraction. The scale of potential short-term changes in the benthos will be limited if the requirement for operators to apply the principle of best available technology is met.

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

6. Assessment methodology impact

The project's impact assessment was carried out in accordance with the **project's framework methodology, as described in Section 5 of Volume I of the report, with some modifications or refinements, as discussed below**.

6.1. Modifications or refinements to the framework methodology evaluation

The following modifications or refinements to the evaluation framework methodology were made in this study.

6.1.1. Sensitivity assessment of species benthos

It was necessary to introduce into the adopted methodology a detailed classification of the sensitivity of benthic species, which is in line with the practiced methodology for assessing the impact on this environmental element, among others in Denmark (Birklund, 2007a, 2009a).

Sensitivity assessment of benthic species was described based on the methodology of Hiscock and Tyler-Walters (2006). Sensitivity of benthic species was defined as a function of the population's ability to adapt to various changes occurring in the environment as a result of the project (known as susceptibility to change) and the population's ability to return to its original state after the cessation of the influencing factor (stressor).

The sensitivity classification of benthic species is shown in the table below.

Table 2. Sensitivity classification of benthic species

Vulnerability to change	Ability to restore populations/return to the original state						
	No	>25 years	> 10-25 years	> 5-10 years	> 1-5 years	< 1 year	< 1 week
None1	very high	very high	high	average	average	low	very low
Low2	very high	high	high	average	low	low	very low
Average3	high	average	average	low	low	very low	no
High4	no	no	no	no	no	no	no

1 - the population will be destroyed under the influence of the stressor

2 - part of the population will be destroyed under the impact of the stressor, and the remaining survival rate will be reduced

3 - the population will not be destroyed under the impact of the stressor, but its survival rate will be reduced

4 - the impact of the stressor does not affect the structure and functioning of the population

Source: Hiscock and Tyler-Walters, 2006

6.1.2. Assessment of the scale of exposure

In determining the scale of exposure of the impact, it was assumed that local scale means the impact on populations of local significance, i.e. limited to the area designated for the project, while regional scale means the impact on populations of regional significance, i.e. pertaining to physical-geographic units (e.g. mesoregions, macro-regions).

6.1.3. Assessment of the importance of resource

Definitions defining the importance of the environmental resource benthos have been revised. An in-house study was used, but based on definitions, criteria and classifications commonly used in benthic research (Dowgiałło and Brzeska, 2009; Węsławski, 2009; Węsławski et al, 2009; Kruk-Dowgiałło et al, 2011; Osowiecki et al, 2012).

The benthos is a group of organisms, so the impact factors (stressors) at the stage of construction, operation and dismantling of the wind farm will affect the entire assemblages/habitats, taking into account the relevance of individual species included in them for the course of ecological processes (e.g., rarity, sensitivity to environmental changes). The importance of the benthos is primarily ecological (functional) importance, that is, either a food role or a habitat-forming role. In addition, the status of the benthic population as an environmental resource is indicative of the ecological quality of marine areas (natural value), which can be assessed by the adopted criteria of natural value in the case of macrophytes (Kruk-Dowgiałło and Brzeska, 2009; Kruk-Dowgiałło et al., 2011) and using the multimetric index B for macrozoobenthos, among others. This indicator combines the results of quantitative measurements (alignment of abundance of individual taxa) and species diversity with qualitative information about the degree of ecological tolerance of individual taxa (Osowiecki et al., 2012).

The importance of the benthos determined separately for phytobenthos and macrozoobenthos on the basis of a 5 - step classification is shown in the following tables (Table 3, Table 4).

For assessing the importance of phytobenthos, the presence of communities, playing a habitat-forming role, is a more important feature than the presence of individual rare or protected species.

Table 3. Classification of the importance of the benthos

Meaning	Habitat-forming role	Presence of rare and protected species
Very small	lack of communities	lack of protected and rare species
Small	lack of communities	protected and/or rare species present
Medium	communities are present	lack of protected and/or rare species
Large	communities are present	protected and/or rare species present
Very large	communities are present	protected and rare species form communities

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

The most important feature classifying the importance of macrozoobenthos is the feeding and habitat-forming role of the assemblages. The macrozoobenthos assemblage usually includes several clusters of benthic fauna, including bivalves, crustaceans, polychaetes, oligochaetes and gastropods, but the highest abundance/biomass or dominance of individual clusters in an assemblage determines its ecological significance (Table 7). The B Index is a multimetric index for assessing the ecological quality of Baltic coastal waters (POM) based on the status of benthic macroinvertebrates. The index was created in accordance with the requirements of the EU Water Framework Directive 2000/60/EC. Index B in its algorithm takes into account: abundance, sensitivity of individual species and the number of species in the assemblage (Osowiecki et al., 2012) and divides water status into 5 classes (Table 4.3. in Blenska et al., 2015 - Volume III Section 6 of the EIA).

Table 4. Classification of the importance of macrozobenthos

Meaning	Food and habitat-forming role	Indicator B	Presence of rare and protected species
Very small	no clams in the band	< 1.91 - poor state of ecological quality of the marine area	no
Small	the team is dominated by polychaetes tolerant to environmental degradation	≥ 1.91 - poor state of ecological quality of the marine area	none/ may occur
Medium	the band is made up of bivalves, polychaetes and crustaceans sensitive to environmental degradation	≥ 2.7 - moderate state of ecological quality of the marine area/ ≥ 3.18 - good state of ecological quality of the marine area	none/ may occur
Large	in the complex there are mainly various species of mussels, including the mussel - *Mytilus trossulus*	≥ 3.18 - good state of ecological quality of the marine area	may occur
Very large	in the assemblage there are various species of mussels, and especially	≥ 3.18 - good state of ecological quality of the marine area / > 3.72 -	may occur

Meaning	Food and habitat-forming role	Indicator B	Presence of rare and protected species
	dense aggregations of mussels - *Mytilus trossulus*	very good state of ecological quality of the area marine	

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

In the classification of the importance of environmental resources, the category "insignificant" does not apply to the benthos, since every biotic element of the ecosystem is more or less important for its functioning. This category was replaced by the "very small" category and taken into account in the final impact significance assessment matrix covering impact magnitude and resource significance, as shown in the table below.

Table 5. Impact significance assessment matrix

Receptor importance (phytobenthos or macrozoobenthos)	Magnitude of impact				
	Large	Moderate	Small	Insignificant	No change
Very large	Very large	Large	Moderate	Small	No change
Large	Large	Moderate	Small	Small	No change
Medium	Moderate	Small	Small	Skip	No change
Small	Small	Small	Skip	Skip	No change
Very small	Small	Skip	Skip	No change	No change

6.1.4. The most far-reaching scenario of the venture - NIS 2015

In the 2015 Report, the assessment of potential impacts of the BIII OWF in the parameters approved by the Environmental Decision was based on the analysis of the most far-reaching scenario of the project - NIS 2015, i.e. such a set of parameters of the Project that negatively affects the benthos to the highest degree. The 2015 NIS assumed the construction of 200 wind power plants (this is the maximum number of plants according to the PSZW) and 7 offshore substations with associated infrastructure, placed on gravity foundations, surrounded by a leaching protection layer. Of the foundations proposed in the technical concept of the Royal Haskoning DHV (2014) - the gravitational one will have the most negative impact on the benthos due to the greatest width of the base. **It was considered that any other project scenario considered, would result in environmental impacts equal to or less than the NIS. The option approved by the Environmental Decision calls for 120 power plants, about 40% less than in the NIS.**

With the modified parameters of the Project vis-à-vis those approved by the Environmental Decision, there will be a further reduction in the number of power plants to 60 units, which is 50% of the number of power plants approved by the Environmental Decision and 30% of the power plants adopted for the NIS. In addition, the possibility of using gravity foundations has been restricted to supporting infrastructure only (foundations for power plants will be implemented as monopile or jacket foundations), and the number of such foundations has been reduced from 6 to 1 unit.

7. Potential impacts of offshore wind farms offshore wind farms

In the following, based on literature data and, above all, those presented in the 2015 Report, the potential impacts of offshore wind farms on benthos have been determined, at different stages of investment. The most important parameters and factors affecting the scale of impacts are also indicated.

7.1. Stage construction

A summary of the main, indirect and direct types of impacts of the wind farm on the benthos during the construction phase is presented in Table 6 (from most to least significant). Individual benthic taxa, depending on their sensitivity, as well as the biology of the species themselves, will tolerate the environmental changes that have occurred to varying degrees, as will be described in detail in Chapter 9 of this section.

Table 6. Potential impacts of OWF on benthos - construction phase

Type of potential impact	Impact on benthos and key parameters and factors affecting the level of impact
Disruption of sediment structure	During the construction of the OWF, work will be carried out that will disturb the structure of the bottom sediments. These include, in particular, the installation of foundations and the laying of power cables, as well as the storage of dredged bottom material. Such disturbances will also be caused by anchoring vessels. This mechanical intervention in marine sediment will physically destroy benthic communities by crushing, scraping, or carrying them to the bottom surface, where they will be subject to predation pressure. (Söker et al, 2000; Meissner and Sordyl, 2006; Zucco et al, 2006; Macnaughton et al, 2014). The most important parameters affecting the level of impact are: • the dimensions and number of foundations to be built, and the number and technique of cables to be laid, • a type of rock material that forms the seabed.
Increase in the concentration of suspended solids in the water depths	As a direct result of the disturbance of the bottom sediment structure, suspended solids will rise and spread in the water tone. Organic and inorganic particles larger than 0.45 µm floating in water form a suspension (Font et al., 1996). Fine particles float longer than larger particles and the range of their dispersion is wide (Hiscock et al., 2002). The higher the concentration of the suspension and the longer its exposure time, the more negatively it affects the condition of benthic organisms (Newcombe and MacDonald, 1991). An increase in suspended solids in the water tone will result in a decrease in water transparency, which adversely affects the photosynthetic process of phytobenthos.

Type of potential impact	Impact on benthos and key parameters and factors affecting the level of impact
	There will be a change in trophic conditions for organisms that filter or feed on suspended solids and organic matter deposited in the sediments. For some species of benthic macroinvertebrates that feed through filtration, a higher concentration of suspended solids will initially lead to an increase in the process and the condition of the organisms (Söker et al., 2000). However, once a species-appropriate threshold of suspended particle concentration in the water is exceeded, there is a rejection of the filtered material in the form of pseudofecal matter or a reduction in the filtration process causing an increase in mortality of benthic fauna, such as by clogging the filter apparatus of bivalves (Widdows et al., 1979; Cowie et al. 2000, Söker et al, 2000; Kooijman, 2006; Leonhard, 2006). Only in centipedes and bryozoans were the aforementioned physiological reactions not observed (Könnecker, 1977). A positive result of this phenomenon may be the release of additional nutrients from the sediments that provide additional food for macrozoobenthos (Schroeder, 1995; Cooper and Beiboer, 2002). The most important parameters affecting the level of impact are: • the dimensions and number of foundations to be built, and the number and technique of cables to be laid, • a type of rock material that forms the seabed.
Deposition of suspended solids on the seabed	Suspended solids raised due to ongoing construction activities will gradually re-deposit on the seabed. The deposition of suspended solids will have an adverse effect on the photosynthetic process of plant organisms. This will result in an increase in the intensity of the burial of vagile macrozoobenthos species from under the additional sediment layer. Epifaunal species and filter-feeders are unable to dig out from under an additional layer of sedimenting suspension greater than 1 cm. Infaunal organisms can tolerate backfilling with a layer between 5 and 10 cm thick, although this also depends on the type of sediment and time of impact (Maurer et al., 1986; Hiscock et al., 2002). However, after a month, there is increased mortality of all benthic species by covering them with a 5 cm thick layer of sand and silt (Söker et al., 2000; Hiscock et al., 2002). The most important parameters affecting the level of impact are: • the dimensions and number of foundations to be built, and the number and technique of cables to be laid, • a type of rock material that forms the seabed.
Release of pollutants and nutrients from the sludge into the water body	Construction work that disturbs the sediment structure promotes the passage of pollutants and nutrients from the

Type of potential impact	Impact on benthos and key parameters and factors affecting the level of impact
	sediment to the water body (Frostner, 1980; Bourg and Loch, 1995; Bojakowska, 2001; Dembska, 2003; Uścinowicz, 2011). From the agitated sediments, labile forms of metals, organic pollutants, i.e. polycyclic aromatic hydrocarbons (PAHs) and polychlorinated biphenyls (PCBs), biogenes (nitrogen and phosphorus), among others, will pass into the water. Harmful chemical compounds exist in marine sediment and water in various forms, but only some of them are assimilated by living organisms causing negative effects (Bryan et al., 1985) in the form of changes in the qualitative and quantitative structure of the benthos. The toxicity of heavy metals or chlorinated hydrocarbons (DDT, PCBs) is due to their accumulation in bottom sediments and subsequently in the downstream trophic chain of marine organisms (Pempkowiak, 1997). As a result, this can lead to a decline in benthic abundance and biodiversity, which will be dominated by opportunistic species (Kingston, 1992; Grant and Briggs, 2002). Accumulation of heavy metals by bivalves is the reason for deformation of their shells, as well as the occurrence of the neoplastic disease gill neoplasia (Hummel et al., 2000; Thiriot- Quievreux and Volovich, 2001). As early as the 1970s, a correlation was noted between the presence of tributyltin (TBT) compounds used as a biocide on ship hulls and the frequency of anomalies in marine mollusks (Wang et al., 2010; Yamamoto et al., 2009). At present, the use of TBTs is banned or explicitly restricted, unfortunately, these compounds accumulate in bottom sediments, where they remain for long periods of time, prolonging the exposure of aquatic organisms to their toxic effects. TBT's mechanism of toxicity is largely directed at reproductive dysfunction, due to its androgenic effects (Gosz et al., 2011). The increased amount of available nitrogen and phosphorus compounds in the water can increase plant biomass. The most important parameters affecting the level of impact are: • dimensions and number of foundations, • the length of the cable sections and the width and depth of the cable trench, • the types and amount of pollutants deposited in bottom sediments, • a type of rock material that forms the seabed.
Oil spill	The release of petroleum substances may occur in emergency situations (ship failure or collision, failure at a substation) and is an unplanned impact. Heavier oil fractions can be sorbed on the surface of organic and mineral suspensions, which will cause their specific gravity to increase and gradually sink to the bottom.

Type of potential impact	Impact on benthos and key parameters and factors affecting the level of impact
	Contamination of water and bottom sediments can negatively affect benthic organisms, causing contamination of organisms at all levels of the food chain in the failure area (Malaczynski and Czarnecki, 2010). The most important parameters affecting the level of impact are: • the type and amount of oil substances released, • weather conditions, • a type of rock material that forms the seabed.
Contamination of the seabed with construction materials	During the construction of the offshore wind farm, the project site will generate waste directly related to with the process of building wind turbine components. These may include damaged parts of the farm's assembled components, cement, grout, mortar, binders used to join the foundation elements and power plant towers, and other chemicals used during construction work. They can enter the sea in an unplanned manner and then be deposited on the bottom. The most important parameters affecting the level of impact are: • the type and amount of waste released, • weather conditions, • a type of rock material that forms the seabed.
Underwater noise emissions	The benthos will be exposed to underwater noise and vibration emissions during the installation of monopile, jacket and tripod foundations. The detrimental effects of these interactions on the physiology of the above organisms are little known, as there are only selective literature data on the results of studies that were conducted under laboratory conditions. The average sound intensity during piling is 133- 145 dB in the frequency range of 50-200 Hz (Leonhard, 2003). Among benthic invertebrates, only crustaceans of the order Decapoda (lobsters, shrimp, garnets, crabs) are sensitive to the low-frequency noise (Budelmann and Young, 1994). In Crangon crangon garnels, exposure of individuals to noise conditions reaching 30 dB (at 25 - 400 Hz) led to a decrease in growth and reproduction rates, and their increased mortality (Lagardere, 1982). In the lobster Homarus americanus, a slowing of the heart rate was observed in the sound frequency range of 10 - 75 Hz at 150 dB (Offut, 1970). The most important parameters affecting the level of impact are: • number of foundations, • diameter of the pile(s), • power of the jackhammer, • piling time.

7.2. Stage operation

A summary of the main types of impacts of the wind farm on benthos during the operation stage is presented in Table 7, from most to least significant. Individual benthic taxa, depending on their sensitivity, as well as the biology of the species themselves, will tolerate the environmental changes that have occurred to varying degrees, as will be described in detail in Chapter 9 of this section of the EIA.

Table 7. Potential impact of the OWF on benthos - operation stage

Type of potential impact	Impact on benthos and key parameters and factors affecting the level of impact
Loss of habitat	The foundations, along with a layer of protection against leaching from offshore wind farms, occupy certain areas of the seabed. The occupation of the bottom by the foundations will continue throughout the life of the farm. There will be a permanent loss of benthic habitat at the site of the farm's underwater installations (foundations and scour protection layer) (Söker et al, 2000; Meissner and Sordyl, 2006; Zucco et al, 2006; Macnaughton et al, 2014). The most important parameters affecting the scale of impact are: • number and diameter of the foundation base, • the width of the leaching protection layer (anti-erosion layer).
The creation of an "artificial reef"	One of the impacts of the OWF at the operational stage will be the "artificial reef" effect. It is formed by a hard and stable foundation for wind turbine foundations along with a leaching protection layer made of stones, boulders or rock ballast (Biowind, 2005). As a result, a new habitat is created through very rapid colonization by plant and animal communities (Norsker, 1997; Newell et al., 1998). This leads to an increase in the biodiversity of biocoenoses and an increase in the food base for fish and diving birds. The increase in biological production of the seafloor is also manifested by an increased load of organic matter in the form of dying organisms or fecal and pseudo-fecal matter of bivalves falling to the bottom (Biernacka, 1972; Mankowski and Rumek, 1975; Qvarfordt et al, 2006; Wilhelmsson and Malm, 2008). The process of succession - overgrowth with macroalgae and invertebrates of underwater power plant structures - begins as early as the first growing season of organisms from the time of plant foundation and relatively stabilizes after about 3 to 5 years, when the longest-lived bivalve species reach maximum size (Metoc Plc, 2000).

Type of potential impact	Impact on benthos and key parameters and factors affecting the level of impact
	In the case of plants, the overgrowth of underwater farm structures (piles) is zonal, determined by light conditions with a maximum depth to about 20 m from sea level, i.e. to the limit of the range of the euphotic zone in the open waters of the Polish Baltic zone (Kruk-Dowgiałło et al., 2011). The species assemblages of the epiphytic flora may include not only species common in Polish marine areas, but also species that are rare, protected or never recorded in Polish waters. Spores of these species or their vegetative forms may be brought with currents to the area of the planned farm from other areas of the Baltic Sea. A clear effect of the OWF's impact on the benthos, as already observed in the example of operating farms in the North Sea, is the process of "mythmaking" (Krone et al., 2013). The hard substrate of the farm's underwater structures is a new artificial element for the macrozoobenthos community, but it differs from the natural one (People, 2006; Wilhelmsson and Malm, 2008). Dominant among the benthic fauna, mussels, through filtration, take an important part in the flow of energy through the ecosystem. The process of biodeposition of suspended matter by mussels is more beneficial to ecosystem functioning than the process of natural sedimentation (Kautsky and Evans, 1987) and are themselves attractive substrates for epifauna, such as Anthozoa corals and Hydrozoa helminths (Riis and Dolmer, 2003; Norling and Kautsky, 2007). The most important parameters affecting the scale of impact are: • number and shape of foundations, • the shape and sidewall area of support structures (piles) below the sea surface, • the surface of the anti-erosion layer.
Changes in the regime of sea currents affecting changes in sediment granulometry	The foundations of the wind turbines, along with the stone scour protection layer, will modify the velocity distribution of ocean currents, also affecting sediment transport (Cooper and Beiboer, 2002; Köller et al, 2006; Zucco et al, 2006). As a result of changes in hydrodynamics and water stratification throughout the farm area, there will also be changes in the granulometry of bottom sediments in the immediate vicinity of the foundations. They, in turn, will cause a reconstruction of the qualitative and quantitative structure of the phyto- and zoobenthic communities in places where the benthos has not been completely destroyed. The most important parameters affecting the level of impact: • the number, dimensions and compaction of foundations.

Type of potential impact	Impact on benthos and key parameters and factors affecting the level of impact
Disruption of sediment structure	During the operation of the OWF, work will be carried out to disturb the structure of the bottom sediments, such as replacing damaged sections of the power cable. Disturbance will also be caused by anchoring vessels. In addition, the bottom sediments in the immediate vicinity of the foundation structures will be washed out. To prevent this from happening, leaching protection called an erosion control layer will be used. The most important parameters affecting the level of impact are: • dimensions and number of foundations, • a type of rock material that forms the seabed.
Change in water and sediment temperature	Installation of cables between wind turbines is associated with heat emissions and temperature increases in the sediment, in extreme cases by as much as several degrees Celsius (Kelvin) in the immediate vicinity of a cable buried more than 1 meter deep in the seabed. Electric current flowing through a power cable causes it to heat up, caused by power losses to resistance, according to Joule's law. With the increase in cable temperature above ambient temperature, heat transfer to the surrounding environment begins. This can lead to changes in oxidation-reduction potential, biogen content, or reduce microbial activity in sediments (Zucco et al., 2006). The data regarding the increase in sediment temperature in the vicinity of the cable connecting the wind turbines comes from conducting various theoretical models. It was noted that the temperature of the sediment increases only in the layer 20 - 30 cm from the surface of the cable buried at a depth of 1 m and does not exceed 2 K (2°C). No deleterious effect of elevated temperatures on benthic organisms has been observed, as these live mostly buried from the sediment surface to a depth of 35 cm (Worzyk and Böngeler, 2003; Brakelmann, 2005). In general, benthic fauna are naturally adapted to large seasonal temperature changes and are not sensitive or show very low sensitivity to a 2°C (2 K) temperature increase (Birklund, 2009). In this case, the impact is poorly documented in terms of effects on physiological and behavioral changes, reproduction and survival of benthic organisms. The most important parameters affecting the level of impact are: • depth of cable burial, • a type of rock material that forms the seabed.
Emission of electromagnetic fields and radiation	Cables that transmit electricity transmit electromagnetic fields. To date, the literature reporting on the potential impact of this parameter on benthic fauna is poorly documented and inconclusive (Andrulewicz et al, 2003; Meissner and Sordyl, 2006; Zucco et al, 2006). Electromagnetic fields can affect the migratory abilities of some crustaceans that are sensitive to the

Type of potential impact	Impact on benthos and key parameters and factors affecting the level of impact
	Earth's magnetic field (Gill et al., 2005), such as in the Baltic subspecies Idotea balthica (Ugolini and Pezzani, 1992). In contrast, no effect of the magnetic field was found on the following crustaceans: the gargoyle Crangon crangon, the American crab Rhitropanopeus harrisi and the great doubloon Saduria entomon based on laboratory experiments (Bochert and Zettler, 2004). The most important parameters affecting the scale of impact are: • the length and type of power cable, • the depth of foundation of the power cable.
Oil spill	See description for construction phase
Contamination of the seabed with consumables	During the operation of the wind farm, the project site will generate waste directly related to the operation of the wind farm. These may include damaged parts of farm components, cement, grout, mortar, operating fluids and other chemicals used or replaced during maintenance work. They can enter the sea in an unplanned manner and then be deposited on the bottom. The most important parameters affecting the level of impact are: • the type and amount of waste released, • weather conditions, • a type of rock material that forms the seabed.
Emission of underwater noise and vibration	At the operation stage of the farm, noise and vibration are associated with the operation of the turbines. The deleterious effects of these factors on the epiphytic fauna colonizing underwater structures of wind turbines are not known (Vella et al., 2001).

7.3. Stage decommissioning

Table 8. Potential impacts of OWF on benthos - decommissioning phase

Type of potential impact	Impact on benthos and key parameters and factors affecting the level of impact
Disruption of sediment structure	During the decommissioning of the offshore wind farm, work will be carried out that will disturb the structure of the bottom sediments. These include, in particular, the removal of foundations and power cables. Such disturbances will also be caused by anchoring vessels.

Type of potential impact	Impact on benthos and key parameters and factors affecting the level of impact
	Dismantling methods depend on foundation types, local environmental conditions, available vessel types and tools (Nedwell et al., 2003). There may be partial destruction of the benthic assemblage that repopulated the farm area during the operation stage around the foundations and over the power cables. Full succession of destroyed habitats can take 3 to 5 years, when the longest-lived species reach maximum size and biomass. The most important parameters affecting the level of impact are: • the number, types and dimensions of foundations, • a type of rock material that forms the seabed.
Increase in the concentration of suspended solids in the water depths	As a direct result of the disturbance of the bottom sediment structure, suspended solids will rise and spread in the water tone. The impact will not differ from the analogous impact during the construction phase. In addition, the disassembly sites will be backfilled with sand.
Deposition of suspended solids on the seabed	As a direct result of disturbing the structure of bottom sediments, the process of sedimentation of suspended solids through redeposition on the bottom will occur. The impact will not differ from the analogous impact during the construction phase. In addition, the disassembly sites will be backfilled with sand.
Elimination of the "artificial reef"	A micro-ecosystem of "artificial reefs" on the hard substrate of wind turbine structures will already be formed during the operation of the farm. If the farm's facilities are removed, not only will the habitat of benthic organisms be destroyed, but also the potential habitat, feeding, shelter and breeding grounds of many fish species and the potential food of birds - bentophagous. The most important parameters affecting the scale of impact are: • number and shape of foundations, • the shape and sidewall area of support structures (piles) below the sea surface, • the surface of the anti-erosion layer.
Release of pollutants and nutrients from the sludge into the water body	During the decommissioning of offshore wind farms, work will be carried out that causes agitation of bottom sediments, such as the removal of foundations, cables and anchoring of ships. They will favor the passage of pollutants and nutrients from the sediment into the water body.

Type of potential impact	Impact on benthos and key parameters and factors affecting the level of impact
	Labile forms of metals, organic pollutants, i.e. polycyclic aromatic hydrocarbons (PAHs) and polychlorinated biphenyls (PCBs), biogenes (nitrogen and phosphorus) can pass into the water. The most important parameters affecting the level of impact are: • number and dimensions of decommissioned foundations and length of cables, • the types and amount of pollutants deposited in bottom sediments, • a type of rock material that forms the seabed.
Oil spill	See description for construction phase
Contamination of the seabed with decommissioning materials	During the decommissioning of the wind farm, the project site will generate waste directly related to the decommissioning of the wind farm. These may include damaged parts of farm components, operating fluids, etc. They can unintentionally enter the sea and be deposited on the bottom. The most important parameters affecting the level of impact are: • the type and amount of waste released, • weather conditions, • a type of rock material that forms the seabed.
Underwater noise emissions	During the decommissioning phase of an offshore wind farm, noise and vibration arise from the demolition of wind turbine structural components and are associated with ship operations. The impact of these sounds on the physiological state of benthic organisms is the same as at the stage of construction of the farm (see: section 7.1.).

8. Species subject to environmental impact assessment environment

This chapter briefly characterizes the benthic organisms found in the area of the proposed OWF BIII. A full characterization is provided in the results of the benthic surveys conducted by the Maritime Institute in Gdansk, which constitute Section 6 of Volume III of the EIA. In addition, the chapter defines the sensitivity of the receptors (phytobenthos and macrozoobenthos) to the most important impacts of the farm and indicates the importance of these two communities to the ecosystem.

8.1. Phytobenthos

Phytobenthos inhabits the bottom of the overexposed zone, where the amount of light ensures that photosynthesis is sustained (Andrulewicz et al., 1998). Plants provide habitat for numerous species of crustaceans, bivalves and ichthyofauna (Węsławski, 2009). Multispecies underwater meadows form diverse plant communities and are a valuable element of the marine environment that increases

biodiversity and the productivity of the water body (Kruk-Dowgiałło and Brzeska, 2009). The function of phytobenthos in stabilizing bottom sediments and preventing coastal erosion is well known (Fonseca, 1989). The structure of the qualitative and quantitative composition of the phytobenthos, including, among other things, information on the presence of rare, protected or habitat-forming species, can also provide information on the state of the studied region of the seabed (Osowiecki and Kruk-Dowgiałło, 2006; Kruk-Dowgiałło et al., 2011).

As a result of the 2013 inventory survey, **phytobenthos was found only in the buffer zone of the OWF area and only on 1% of the area of the entire study area.** 4 taxa of phytobenthos (macroalgae) were identified, which mostly sparsely overgrow (coverage < 1%) unattached to the bottom aggregations of mussels, moving freely on the sand with the sea currents (vegetation temporarily present in the area). Single plant specimens attached to boulders and pebbles (permanent vegetation in the area) were found in only two locations, in the 23 - 25 m depth range. It was a filamentous *kelp* probably from the family *Rhodomelaceae* (Blenska et al. 2014). All phytobenthic species were subjected to impact assessment.

The characteristics of phytobenthic species subject to impact assessment are shown in Table 9.

Table 9. Characteristics of phytobenthic species subject to impact assessment and found in June 2013 in the BIII offshore wind farm area and the one-mile buffer zone

Lp.	Species Latin name/ customary	Cluster Latin/common name	The habit of the mold	Reproduction	Environmental preferences	Occurrence in POM	Occurrence * in the buffer zone of the OWF
1.	*Ectocarpus siliculosus* (Dillwyn) Lyngbye 1819/ Siliceous spikelet	Ochrophyta browns	The mold is yellowish or brownish, irregularly fork-branched, up to 30 cm high.	Annual plant. It reproduces vegetatively by producing spores and fragmenting the mold, from May to July.	Hard substrate (pebbles, shells), algae and vascular plants to which it attaches. It floods on the bottom and/or floats in the depths of the water in the form of mats (very often co-occurs with P. littoralis).	A common species, noted in the Puck Bay and areas of rocky bottoms in open waters (e.g., the boulder field of Slupsk Shoal, Ditches).	Accessory
2.	*Pylaiella littoralis* (Linnaeus) Kjellman/ Coastal *Pylaiella*	Ochrophyta browns	Brown mold composed of alternate branching threads, not twisted together or loosely twisted, up to 40 cm high.	Annual plant. It reproduces vegetatively by producing spores and fragmenting the mold.	Hard substrate (pebbles, shells), algae and vascular plants to which it attaches. It settles on the bottom and/or floats in the depths of the water in the form of mats (very often co-occurs with E. siliculosus).	A common species, noted in the Puck Bay and areas of rocky bottoms in open waters (e.g., the boulder field of Slupsk Shoal, Ditches). Water eutrophication index.	Accessory
3.	*Polysiphonia* sp. - the most commonly recorded in POM: *Polysiphonia fucoides* (Hudson) Greville 1824/	Rhodophyta crayfish	Dark red mold branching in a rod-like fashion, up to 25 cm high.	Perennial plant. It reproduces vegetatively by producing spores, and bears fruit in spring and summer.	Hard substrate (pebbles, shells) to which it attaches.	A species common to rocky bottoms, recorded in the Puck Bay and in open waters (e.g., the boulder pit of Slupsk Shoal, Ditches).	Accessory

Lp.	Species Latin name/ customary	Cluster Latin/common name	The habit of the mold	Reproduction	Environmental preferences	Occurrence in POM	Occurrence * in the buffer zone of the OWF
	The hermaphrodite						
4.	*Rhodomela confervoides* (Hudson) P.C.Silva, 1952/ None	Rhodophyta crayfish	Purple or brownish-red mold, alternately branched, debarked, up to 20 cm high.	Perennial plant. It bears fruit in autumn and winter. It reproduces mainly by producing spores, rarely by fragmenting the mold and sexually.	Hard substrate (pebbles, shells), larger algae to which it attaches.	A rare species, recorded in the rocky bottom regions of the Puck Bay and open waters (e.g., the boulder bed of Slupsk Shoal).	Fixed

* The nature of the occurrence of a given species in the study area was determined on the basis of the constancy index (Trojan, 1980), according to which taxa recorded at 0-25% of stations were considered incidental, 26-50% - accessory, 51-75% - constant, 76-100% - absolutely constant.

8.2. Macrozoobenthos

The macrozoobenthos includes the clusters:*bivalves (Bivalvia*),*crustaceans (Crustacea*),*polychaetes (Polychaeta*), scorpionfishes (*Oligochaeta*) and gastropods*(Gastropoda*). The importance of the macrozoobenthos of an area for the integrity of the Baltic ecosystem consists of the uniqueness of the area, the abundance of species and individuals, the condition of the community of organisms, the presence of habitat-forming species or those performing other functions for the benefit of the ecosystem, such as the oxygenation of the sediment by burrowing organisms, the provision of shelter or food (Węsławski, 2009). Bivalves are often the most important component of the benthic macrofauna. They play a very important role, filtering and purifying huge amounts of bottom water. Bivalves, polychaetes and crustaceans are fed by bentophages: fish and seabirds (Zmudzinski, 1990). Bivalve eggs and larvae are food for zooplankton and fish larvae (Szaniawska, 1991). Belonging to the mussel family, the mussel - *Mytilus trossulus* feeding on organic suspended solids filtered from the water tone (biofilter) locally increases water transparency and contributes to reducing the effects of water body overfertilization (eutrophication). The concentration of this species provides a favorable habitat for a diverse associated fauna, consisting mainly of crustaceans and many other small invertebrates (Kruk-Dowgiałło et al., 2011). A different type of benthic assemblages is formed by polychaetes, as organisms that feed on organic matter from the sediment and positively transform the physical and geochemical structure of the sediment through bioturbation (life activity in the seabed, such as scrambling in the sediment) (Osowiecki and Kruk-Dowgiałło, 2006).

Among the macrozoobenthos, 27 species and higher (not designated to species) taxonomic units were found. No rare or protected species were found. The taxonomic composition, abundance and biomass of the macrozoobenthos were typical of the shallow to intermediate deep bottom of the open zone of the southern Baltic Sea in both the BIII OWF area and the one-mile buffer zone. Accordingly, the species most common in the area under evaluation, i.e. occurring at more than 25% of the stations surveyed, were selected for the environmental assessment. They are represented by 12 species belonging to 5 clusters*(Polychaeta, Oligochaeta, Malacostraca, Gastropoda, Bivalvia*) occurring absolutely continuously (76 - 100%), continuously (51 - 75%) or accessorially (26 - 50%) in the study area, with abundances ranging from 10 to 669 $^{\text{sediments/square}}$ meter and biomasses from 0.05 to 27.82 $^{\text{g/m2}}$ (Trojan 1980, Bleńska et al. 2014).

Characteristics of macrozoobenthos species subject to impact assessment are shown in Table 10.

30 | S t r o n g

Table 10. Characteristics of macrozoobenthos species subject to environmental impact assessment and found in the summer of 2013 and spring of 2014 both in the relevant area of the farm and in the buffer zone of OWF BIII

Lp.	Species Latin/common name	Cluster Latin/common name	Biology and ecology	Occurrence and population status in Polish marine areas	BIII offshore wind farm area with one-mile buffer zone	
					Occurrence*	Abundance/Biomass (average values)
1.	Hediste diversicolor/ Nereida	Polychaeta Polychaetes	• a predatory polychaete that builds habitable tubes in the sediment or crawls along the bottom and plants; a detritophage • euryhaline species, tolerating periodic decrease in oxygenation of bottom water • playing an important role in bioturbation processes; a component of the diet of flatfish	• commonly found along the entire Polish coast, especially in shallow water areas • inhabiting mainly sands and silts • occurring in smaller numbers on the barren sands of the open sea and Slupsk Shoal, where individuals reach relatively small sizes	Absolutely constant	35 pers. $\cdot^{m-2}$/ 1.02 g m. m. $\cdot^{m-2}$
2.	Pygospio elegance/ Pygospio	Polychaeta polychaetes	• a small polychaete that builds long, flexible habitable tubes from sand grains and shell debris, rising above the surface of the bottom • propagating in early spring	• very common throughout the sandy bottom POM, often in significant density • most abundant inhabiting shallower bottoms • forming numerous concentrations both on the barren sands of the open sea and on the organic matter-rich	Absolutely constant	669 pers. $\cdot^{m-2}$/ 0.94 g m. m. $\cdot^{m-2}$

Lp.	Species Latin/common name	Cluster Latin/common name	Biology and ecology	Occurrence and population status in Polish marine areas	BIII offshore wind farm area with one-mile buffer zone	
					Occurrence*	Abundance/Biomass (average values)
				bottom of Gdansk and Pomeranian bays		
3.	Marenzelleria neglecta / Marenzelleria	Polychaeta polychaetes	• non-native invasive species in the Baltic fauna - representative of infauna • by building burrows up to 25 cm deep, it plays an important role in bioturbation processes • feeding on particles suspended in the water depths or detritus from the sediment surface • food for many species of fish	• occurring in large numbers throughout the POM, both on sandy and silty bottoms, to a depth of 80 m • the maximum size (2000 - 3000 persons $^{/m2}$) • was found in the Gulf of Gdansk	Absolutely constant	236 pers. .$^{m-2/}$ 4.80 g m. m. .$^{m-2}$
4.	Oligochaeta non det./ Angiosperms	Oligochaeta scorpionfishes	• scorpionfish with a strongly elongated, cylindrical body with clearly distinguishable segments • detritus-eating hermaphrodites	• living mainly on the sandy bottom of the coastal zone, and partially on the muddy bottom of deeper regions of the sea	Accessory	69 pers. .$^{m-2/}$ 0.07 g m. m. .$^{m-2}$
5.	Saduria entomon / Double great	Malacostraca armored ships	• the largest Baltic crustacean, a relict species of Arctic origin • inhabiting cold and often poorly oxygenated waters	• preferring mainly deeper bottoms, below the 40-50 m isobaths	Accessory	25 person .$^{m-2/}$ 1.46 g m. m. .$^{m-2}$

Lp.	Species Latin/common name	Cluster Latin/common name	Biology and ecology	Occurrence and population status in Polish marine areas	BIII offshore wind farm area with one-mile buffer zone	
					Occurrence*	Abundance/Biomass (average values)
			• feeding on detritus and carrion • an ingredient in the food of juvenile and adult cod	• showing no preference for sediment type (both sandy and muddy bottoms) • the highest concentrations are observed on the slope of the Hel Peninsula and the Slupsk Trough		
6.	Bathyporeia pilosa/ Sandfly	Malacostraca Armored Carriers	• transparent crustacean sensitive to oxygen deficits - an indicator of coastal water quality • feeding on the surface of sediments, eating algae and small invertebrates • reproducing in spring and summer • one of the most important species in the food of young bottom-feeding fish	• massively occurring on the sandy bottom of the coastal zone and shoals, to a depth of about 25 - 30 m • preferring habitats with high water dynamics, clean and non-growing sands • the highest densities were found on the slope of the Hel Peninsula and on the Oder and Slupsk Shoal	Accessory	24 person .$^{m-2}$/ 0.05 g m. m. .$^{m-2}$
7.	Monoporeia affinis/ Black-eyed Pontoporeia	Malacostraca Armored Carriers	• black-eyed amphipod crustacean • requiring a well-oxygenated environment with low temperatures and relatively low salinity	• common throughout the oxygenated area of the Polish zone, ranging in depth from about 10 to 70 m • in the zone of cold waters (about 30-70 m) forms	Accessory	10 person .$^{m-2}$/ 0.07 g m. m. .$^{m-2}$

Lp.	Species Latin/common name	Cluster Latin/common name	Biology and ecology	Occurrence and population status in Polish marine areas	BIII offshore wind farm area with one-mile buffer zone	
					Occurrence*	Abundance/Biomass (average values)
			• making vertical migrations to the sea surface at night • detritophage • an important ingredient in the food of pelagic and demersal fish	concentrations of up to 6,000 os./m2 • in the winter, swimming up to shallower areas		
8.	Hydrobia sp./ Hydrilla	Gastropoda snails	• some of the smallest Baltic snails with shell heights up to about 10 mm • reproducing mainly in spring • h. ventrosa, H. ulvae and H. neglecta are found in the Baltic Sea	• widely distributed, common Baltic snails, distributed to depths of up to 50 m • showing no specific preference for sediment type, more often found on muddy, rocky bottoms and among bottom vegetation	Fixed	90 person .m-2/ 0.15 g m. m. .m-2
9.	Mytilus trossulus/ Musselshell	Bivalvia clams	• mussel shell reaching a maximum of 55 mm • adult specimens attaching themselves to the substrate with byssal threads • biofilter, helping to reduce the effects of eutrophication • reproductive period falling in spring and early summer	• the bathymetric range of the mussel is determined by the presence of hard substrate and the availability of phytoplankton, which rarely occurs below the picocline • in POM inhabiting the boulder bed of the Slupsk Shoal in large numbers (up	Accessory	343 pers. .m-2/ 27.82 g m. m. .m-2

Lp.	Species Latin/common name	Cluster Latin/common name	Biology and ecology	Occurrence and population status in Polish marine areas	BIII offshore wind farm area with one-mile buffer zone	
					Occurrence*	Abundance/Biomass (average values)
			• the concentration of this species provides a favorable habitat for diverse associated fauna (e.g. barnacles, bryozoans) • an important ingredient in the food of flat fish, bull goby, many wintering birds, especially coots and ducks	to 3,000 os./m^2) and the sandy bottoms of the western parts of the Pomeranian and Gdansk Bays • on the sandy bottom forming aggregations of a dozen-odd individuals connected byssus, in the rest of the Polish zone only single individuals are encountered		
10.	Macoma balthica/ Baltic hornwort	Bivalvia clams	• a small Baltic clam that inhabits the surface layer of the bottom, projecting the ends of two siphons to the surface • feeding on detritus and food particles filtered from the water depths • species very resistant to oxygen deficiency • the staple food of flounder, eelgrass, as well as many diving birds, such as ducks	• in POM occurring throughout the bottom, both sandy and silty, to a depth of 90 m • the most abundant inhabiting the muddy bottom of the Gulf of Gdansk, reaching maximum abundances of more than 5,000 os./m^2 • numerous clusters also form in the Pomeranian Bay, on the sandy and silty bottom near the mouth of	Absolutely constant	45 pers. ./m^{-2}/ 13.99 g m. m. ./m^{-2}

The aforementioned species formed two bands. Band I - with the dominant edible mussel Mytilus trossulus occurred in the northern part of the project area, while Band II with the dominance of the pogyspio polychaete Pygospio elegans predominated in the rest of the project area, as shown in Figure 3. The area covered by Complex I is 20.3 square kilometers, which is nearly 11% of the area of OWF BIII, along with a one-mile buffer zone. To the south, the area settled by Complex I is adjacent to a small area dominated by a 16.6-square-kilometer rocky bottom. The remaining central and southern sandy area of the farm is dominated by Band II. The area occupied by this complex is 148.3 square kilometers.

Areas P1 and P3 are outcrops of glacial till with a variable sand and gravel cover, and with numerous stonewalls on the surface. A compact sediment such as clay is difficult to dilute and change morphology under natural conditions. Due to the discontinuous layer of sands and gravels of variable thickness and the compact structure of the clay, the susceptibility to agitation of the surface sediment is low. Areas P1 and P3 provide suitable substrate for the existence of sessile benthos (e.g., blue mussel). Areas covered with stonewalls and boulder fields are feeding areas and shelter for fish.

Areas P2 and P5 (silty-muddy sediments with a thick cover of sandy sediments), as well as area P4 (glacial till covered by a layer of sandy sediments with single boulders on the surface), constitute a substrate that is not very stable, so it is necessary to replace it before the foundations are laid. Vulnerability to surface sediment agitation and disturbance is medium to high. Areas of fine-grained sediments (P2, P5, much of P4) are not a good substrate for the existence of bottom-attaching organisms (bivalves), while they create suitable conditions for organisms that scramble or burrow in the seabed. Due to the lack of shelter for fish, these areas are not good feeding grounds for fish.

8.3. The state of knowledge about the benthos occurring in the project area project

The area where the project is intended to be implemented had not been surveyed for the occurrence and structure of phytobenthos until the 2013 inventory survey, while it had been recognized fragmentarily regarding macrozoobenthos. On the one hand, the oldest literature data concern the assemblages of invertebrate benthic fauna of only the neighboring region of OWF BIII - the eastern slope of Slupsk Shoal, but there are selective data from the farm area itself (Warzocha et al. 2009).

Studies of the eastern slope of the Slupsk Shoal were undertaken by Demel and Mankowski (1951), Zmudzinski (1978) and Warzocha (1995) with the goal of identifying the macrozoobenthos of the bottom of the coastal zone of the open Baltic Sea.

Demel and Mankowski (1951) found that the benthic assemblages found there on a sandy bottom with an admixture of gravel and stones were the poorest among those they studied in the South Baltic. The presence of species such as: baltic hornworm Macoma balthica, sand clam Mya arenaria, common cockle Cerastoderma glaucum, garnela Crangon crangon, pygospio Pygospio elegans in the number of about 10 individuals per $1^{m2\ of}$ bottom surface (samples were taken with a Petersen-type bottom scoop), only at the station located in the eastern part of Slupsk Shoal the shoals of mussel Mytilus (edulis) trossulus reached 158 os./1^{m2}, while the abundance of the same species in other areas of the Baltic Sea was from 10 to even 200 times higher depending on the species.

Zmudzinski (1978) also found that along open seashores the shallow-water benthic fauna is not very diverse.

Based on research conducted in the 1980s. (Warzocha 1995) found three benthic communities there: Macoma balthica (Baltic hornwort) - Mya arenaria (sand clam) along with numerous polychaetes (Polychaeta) such as Pygospio elegans (pygospio), Macoma balthica (Baltic hornworm) - Saduria (Mesidotea) entomon (great double), and the assemblage Mytilus (edulis) trossulus (mussel) - Gammarus salinus (Baltic gudgeon) characteristic especially of the sandy-stone bottom of the eastern slope of Slupsk Shoal.

Recent literature data on the benthic fauna living precisely in the area of the foundation of OWF BIII is very sparse and scarce. The results from 1978 - 2007 only confirm the trend that in the planned area of OWF BIII such species as: Bathyporeia pilosa (sandpiper), Corophium volutator (common snipe), Hediste

diversicolor (nereid), Macoma balthica (Baltic hornwort), Mytilus trossulus (mussel), Monoporeia affinis (black-eyed pontoporeia), Pygospio elegans (pygospio), form low densities compared to the rest of the South Baltic (Warzocha et al. 2009).

Currently, none of the State Environmental Monitoring stations are located in the area of the planned project (Miętus and Sztobryn 2011). The most recent results obtained from benthic surveys conducted in June and November 2013 in the area of the planned farm site are presented in a separate results report (Blenska et al. 2014). Conducting this inventory study was very important to supplement the existing data on the distribution and qualitative-quantitative status of the benthos, including the phytobenthos in the area of the planned BIII offshore wind farm.

8.4. Sensitivity of the benthos to potential impacts of the of the project

The sensitivity of the benthic species selected for the EIA to the **most important** potential impacts for these marine organisms at the stage of construction, operation and dismantling of the offshore wind farm is shown in Table 11. A classification of species sensitivity based on the categories in Table 3 was used, in accordance with the methodology practiced, among others, in Denmark (Birklund, 2007a, 2009a), and this one is based on studies by Hiscock and Tyler-Walters (2006) and biological data updated by the *Marine Biological Association of the UK*[1].

The sensitivity of the benthos depends on the type of impact and on preferences based on the biology of the species itself. As such, it will vary from one species to another during the next stages of the project.

During the construction phase of the farm, the most destructive impact on the benthos is the physical removal of bottom sediments leading to the destruction of the benthos at the foundation site and the internal cable system between the wind turbines. The sensitivity of all benthic species at this stage of the project will be the highest, as it depends on the tolerance of a species' population to the magnitude and duration of the impact, as well as the ability of the population to return to its original state after the cessation of the impact factor (stressor). In the Baltic Sea, it will be a time of rebirth for the longest-lived clams, up to 5 years. During and after the construction period of the farm, photosynthesizing macrophytes and filter-feeding invertebrates will be sensitive to the growth of suspended solids and subsequent sedimentation. The same sensitivity of the benthos will occur at the dismantling stage of wind turbines.

At the stage of operation of the farm, the sensitivity of benthic species to changes in current flow in the area of the farm was considered.

8.5. Meaning benthos

The importance of the benthos to the ecosystem is shown in Table 12 below. An in-house study was used, but based on definitions, criteria and classifications commonly used in benthic research (Dowgiałło and Brzeska, 2009; Węsławski, 2009; Węsławski et al, 2009; Kruk-Dowgiałło et al, 2011; Osowiecki et al, 2012). The importance of the benthos was determined **separately for the phytobenthos and macrozoobenthos** based on the 5 - step classification scale presented in the methodological chapter 6.2.3. (cf: Table 3 and Table 4).

The importance of **phytobenthos** occurring only in the buffer zone (on 1% of the total area under consideration) was determined to be **low**. Vegetation here did not form communities, it occurred in the form of single specimens overgrowing very sparse mussel aggregations not attached to the bottom. These aggregates moved freely on the sand along with the sea currents, so it can be assumed that they come from other areas than the IMF study area. Only one protected species (forkbeard) was encountered.

The significance of the **macrozoobenthos** of the buffer zone and the right area of OWF BIII, where no rare or protected species were found, is **medium**. The two assemblages highlighted, Mytilus trossulus and Pygospio elegans, included bivalves that play a significant food and habitat-forming role in the Southern Baltic, but also polychaetes and crustaceans sensitive to environmental degradation. These assemblages were characterized by a similar degree of natural valuation expressed by the average value of the B index - 3.01 and 3.05 (cf. the report with the results of benthic surveys, Appendix G to the Report).
The categorization of the importance of each resource is shown in the table below.

Table 12. Determination of the importance of phytobenthos and macrozoobenthos occurring in the area of OWF BIII for the functioning of the ecosystem

Receptor	The importance of the receptor (resource)
Phytobenthos	Small
Macrozoobenthos	Medium

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015.

9. Assessment of the impact of OWF BIII on benthos

This chapter assesses the impact of the proposed changes and updates to the parameters of the Project - OWF BIII, on benthos.

Not all of the potential impacts described in Chapter 7 have been subjected to an environmental impact assessment. The impact of noise and vibration on benthos was not considered due to too sparse literature data, as well as a lack of expertise. The assessment conducted at this stage for these impacts would be speculative.

The assessment of the impact of the benthos inhabiting the project area was carried out separately for phytobenthic species (buffer zone), as well as for two types of macrozoobenthic communities (Complex I - *Mytilus trossulus*; Complex II - *Pygospio elegans*). Due to the same ecological importance (average) of the two macrozoobenthos assemblages, as well as the similarity of sensitivity of the species that compose them, the benthic impact assessment was ultimately divided based on phyto- and macrozoobenthos only.

9.1. Stage construction

During the construction of the BIII OWF, work will be carried out that will directly or indirectly affect the benthos. The most significant of these are:

- drilling performed during geotechnical studies,
- preparation of the bottom before the installation of the foundation, including dredging the bottom, removing a layer of sediment about 2-3 m thick and replacing it with rock material with greater bearing capacity (only if gravity foundations are used),
- drilling or driving foundations (only if monopiles, jacket or tripod foundations are used);
- burying cables in the seabed,
- heaping of rock material serving as protection against leaching,
- storage of excavated material from the preparation of the bottom for foundations,
- anchoring jack - up platforms and support units during the assembly of farm components.

A full description of the construction work can be found in Section 4 of Volume II of the EIA.

The following impacts on benthos are expected to occur at the construction stage of OWF BIII:

1) disruption of sediment structure,
2) an increase in the concentration of suspended solids in the water tone,
3) sedimentation of suspended solids on the seabed,
4) the release of pollutants and nutrients from the sediment into the water body.

There may also be unplanned impacts during the construction of the farm, particularly contamination of the water table and bottom sediments:

1) petroleum substances,
2) antifouling agents,
3) accidentally released municipal waste or domestic sewage,
4) accidentally released chemicals and waste from the operation of the farm, which may indirectly affect the benthos.

Unplanned impacts are assessed in Chapter 11.

9.1.1. Disruption of the structure of sediments

During the construction of offshore wind farm BIII, there will be works that cause local disturbance of the structure of the bottom sediments. These include, in particular, the installation of foundations and the laying of power cables. Disturbance will also be caused by anchoring vessels and driving the legs of ships and jack - up barges into the seabed to stabilize their position.

These works will cause physical destruction of benthic organisms that inhabit bottom sediments in construction sites and their immediate vicinity. This is especially true for macrozoobenthos, as phytobenthos was only recorded in the buffer zone of the farm during the environmental studies.

The largest area of the seabed will be affected if gravity foundations are used and will vary depending on the option considered. It is also assumed that the bottom area disturbed by the laying of internal power cables will be the same regardless of the variant (despite differences in distance between power plants, the sum of the lengths of individual cable sections will remain the same). A comparison of the predicted area of seabed disturbance, where total or partial destruction of benthic assemblages will occur under the different alternatives, is presented in the table below.

Table 13. Comparison of the disturbed area of the seabed being the area of mechanical destruction of benthic assemblages for the parameters constituting the 2015 NIS, the conditions approved by the Environmental Decision and for the updated parameters of the Project

Parameter	Parameters that constitute the NIS 2015	Parameters resulting from the Environmental Decision	Updated parameters of the Project
Diameter of the base of the power plant foundation	40 m	50 m	10 m
The width of the leaching protection layer from the edge of the power plant foundation	15 m	15 m	20 m
Diameter of the base of the substation foundation	40 m	50 m	50 m
The width of the leaching protection layer from the edge of the substation foundation	15 m	15 m	15 m
Bottom surface disturbed during the installation of one power plant foundation with a leaching protection layer	3848^{m2}	5027^{m2}	1963^{m2}
Bottom surface disturbed during installation of one substation foundation with leaching protection layer	3848^{m2}	5027^{m2}	5027^{m2}
Maximum number of foundations (power plants and substations)	208 (including 7 stations)	126 (including 6 stations)	61 (including one station)
Bottom surface disturbed with installation of all foundations including leaching protection layers	800 384^{m2}	633 402^{m2}	122 807^{m2}
Total length of sections of internal power cables	200 km	200 km	200 km
Cable trench width	1,5 m	1,5 m	1,5 m

The set of Project parameters constituting the most far-reaching scenario of the 2015 NIS, which was the basis for conducting the environmental impact assessment in the 2015 Report and formed the basis for issuing the Environmental Decision, was considered to be the variant that predicted the possibility of destroying the benthos over an area of about 1.1 km^2. Since the total area of the farm, designated in the PSZW is approx. 117 km^2, of which the development area will be no more than 94 km^2, (89 km^2 indicated in the 2015 Report with a different definition of the development area), and taking into account the exclusion of part of the area of OWF BIII, for the purpose of creating an unobstructed migration corridor for birds between the groupings of wind power plants, belonging to the projects located on the northern and northeastern slopes of the Slupsk Shoal is about 88 km^2, the destruction of the benthos may occur, even in the most far-reaching NIS 2015 scenario, on an area of only about 1.12% of the farm area, while in the case of the modified variant approved by the Environmental Decision it will be an area representing about 0.5% of the farm area.

Works related to the installation of the power plant's foundations will lead to the physical destruction of the organisms inhabiting this surface, which can burrow into the bottom up to a depth of 35 cm, as determined by the biology of individual macrozoobenthos species (Brakelmann 2005).

In total, the hard bottom accounts for about 20% of the area of the BIII offshore wind farm and buffer zone. Assuming a uniform distribution of wind turbines and with the implementation of the Project in the parameters adopted for the 2015 NIS, there will be a loss of hard bottom habitat under about 41 foundations including the protective layer, which accounts for 0.155 $km^2$and 0.17% of the area of OWF BIII, and a loss of soft bottom habitat under about 167 foundations including the protective layer accounts for 0.635 km2^{and} 0.71% of the area of OWF BIII.

Macrozoobenthos biomass in the BIII OWF area ranged widely, from 4.03 g to 757.34 g per 1m^2 (at station 10, where dense mussel aggregations were found). Maximum biomass values were found in the northwestern part of OWF BIII (cf: Figure 3 and Figure 4 in Chapter 8), which is associated with the presence of the mussel Mytilus trossulus on the bottom of coarse sediments and rocky bottoms (Bleńska et al. 2014).

If the average biomass of the Mytilus trossulus assemblage (clams and polychaetes) was 125.26 g/m^2, then under a single gravity foundation including a leaching protection layer of 3800m^2, there will be a permanent loss of biomass of this assemblage equal to 476 kg. Since the complex occupies only 11% of the area of the right area and buffer zone of the BIII OWF (Blenska et al. 2014), then in the NIS, assuming an even distribution of foundations, there could be a loss of biomass under only 22 foundations, which would amount to 10,472 kg.

For the Pygospio elegans (polychaetes, bivalves and crustaceans) assemblage characteristic of the majority of the sandy area of OWF BIII (80%), the average biomass was 34.85 g/m^2 (Blenska et al. 2014). Under one gravity foundation with a leaching protection layer of 3,800m^2, there will be a permanent loss of biomass of this assembly equal to 132 kg, but in NIS 2015, assuming a uniform distribution of foundations, there could be a loss of biomass under 166 foundations, which will amount to 21,912 kg.

The values given above are for the most far-reaching scenario (NIS 2015). If gravity foundations are used in the variant approved by the Environmental Decision (a maximum of 126 foundations in total), the numbers will be about 40% lower.

The disturbance of the bottom sediments in the immediate vicinity of the foundation and cable site will lead to partial destruction of the bottom communities at the site, but with an area smaller than the area of permanent degradation. In this case, the mortality of organisms brought to the surface of the sediment, where they will be subject to increased pressure from predators, mainly fish, may also increase.

The ability to restore the population of benthic communities to their original state applies to areas of the seabed where there has been no permanent degradation, that is, in the immediate vicinity of the foundations and along the internal connection infrastructure, as the site will be backfilled with sandy sediment.

The sensitivity of most macrozoobenthic organisms inhabiting the area considered for the project to physical disturbance of the seabed is medium, which means their low susceptibility to change and ability to restore the population to its original state after about 5 years. It is in the fifth growing season after degradation that the longest-lived clam species will reach maximum size. The sensitivity of crustaceans of the Malacostraca armadillo cluster to physical disturbance of the seafloor is low, as these mobile species can avoid adverse environmental conditions by escaping, so their mortality rate will be lower. Among bivalves, the *Cerastoderma glaucum* heartworm is the most vulnerable, as it is characterized by a slow recovery of the population.

Considering that even in the furthest-reaching NIS 2015 scenario, the significance of impact at the OWF construction stage on macrozoobenthos is low, and no changes are expected in the case of phytobenthos, minimization measures are not required.

Physical destruction of zoobenthos resulting from disturbance of bottom sediment structure is a direct, negative impact of local extent at the construction stage, long-term, i.e. it will last longer than 3 growing seasons, irreversible, repeatable during the construction period, with very high intensity. In the case of phytobenthos, there will be no loss of the resource or impact on its structure and functioning. This means that the natural qualities of the farm area will not change at this stage of the project and are very good in the southern, sandy part of the farm and slightly worse in the northern and central area of OWF BIII (Bleńska et al. 2014).

An assessment of the significance of this impact for the most far-reaching NIS 2015 scenario, which formed the basis for conducting the assessment for the Environmental Decision, is presented in Table 14 below.

In the case of the updated parameters of the BIII OWF , about 30% of the number of power plants envisaged in the NIS 2015 will be built, in addition, the possibility of using gravity foundations for power plant foundations has been excluded, while the number of foundations for related infrastructure - substations has been reduced from 6 to 1 unit, thus, violations of the structure of the bottom sediments leading to physical destruction of the benthos will occur on a significantly smaller area. It is recognized, thus, that the impacts caused by the updated parameters of the Project will be significantly less than both those assessed for the 2015 NIS and the variant approved in the Environmental Decision.

Table 14. Impact assessment involving physical destruction of benthos resulting from disturbance of bottom sediment structure (construction phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Phytobenthos	Small	Low or medium	During the construction of the farm, the structure of the bottom sediments will be disturbed, leading to the physical destruction of the benthos	No change (no loss of the resource, no impact on the structure and operation of the resource)	No change (magnitude of impact -no change, importance of resource - low)
Macrozoobenthos	Medium			Moderate (scale of exposure - local, duration - long-term, intensity - very high)	Small (magnitude of impact - moderate, importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015.

Thus, it should be considered that both the nature of the impacts does not change and their scope and magnitude are smaller than in the case of the variant approved by the Environmental Decision, and thus the change in the parameters of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.1.2. An increase in the concentration of suspended solids in water water

As a direct result of the disturbance of the bottom sediment structure, suspended solids will rise and spread (resuspension) in the water tone. For the 2015 Report, a suspended solids spread model was performed for all project alternatives considered in the 2015 Report. The figures below show the extent of suspended solids spreading and concentration above the bottom, under typical summer conditions, during the construction of gravity foundations.

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015.

A model of the distribution of agitated sediment in the BIII offshore wind farm area shows that there will be an increase of fine sediment (medium dust; diameter < 64 µm) in the water tone at 3% (Lech-Surowiec et al. 2015), which is negligible.

Dwarf algae identified in the buffer zone of OWF BIII have medium, and brown algae have low sensitivity to the described factor. The increase in suspended solids in the water depth will temporarily reduce the access of light (decrease in water transparency), used in photosynthesis by plants. However, there should be no greater disturbance of the qualitative and quantitative structure of macroalgae than what naturally occurs in the environment (agitation of sediments by bottom currents, storms). Thus, it should be concluded that the significant impact of the increased concentration of suspended solids in the water tone on phytobenthos is negligible.

Most macrozoobenthic organisms do not show sensitivity or have very low sensitivity to elevated concentrations of suspended solids, the concentration of which above the bottom in the area of OWF BIII will not exceed 20 mg/L, which corresponds to the range of natural variability of suspended solids concentration in the area (Lech-Surowiec et al. 2015).

Dispersion of suspended solids will be local, extending to the southern buffer zone of the BIII OWF, where single specimens of phytobenthos have been found. The concentration of suspended solids in this area will not even exceed 10 mg/L (Lech-Surowiec et al. 2015). The importance of phytobenthos in the buffer zone of the BIII OWF is very low. Approximately 99% of the area of the BIII offshore wind farm, including the one-mile buffer zone, has unfavorable environmental conditions for phytobenthos development (depths of more than 25 m). The benthic flora, among which no rare or protected species were recorded, was found in 1% of the study area. The vegetation was mostly overgrown (coverage < 1%) by aggregations of mussels carried by currents from place to place. Such phytobenthos does not form communities, does not play a habitat-forming role and is characterized by negligible natural values.

A higher concentration of suspended solids in the water means an increase in its turbidity and a reduction in the photosynthetic process of plant organisms, as well as hampering trophic conditions for filtering macroinvertebrates. In their case, the filtration apparatus can become clogged, leading to death (Moore 1977). However, benthic organisms can survive for a month under conditions of very high suspended solids concentrations of up to 100 mg/L (Berglund 2009).

Given that even in the most far-reaching scenario - NIS 2015, the significance of the impact at the OWF construction stage on the benthos was assessed as negligible, minimization measures are not required.

An increase in the concentration of suspended solids in the water, resulting from the disturbance of the bottom sediment structure during the construction phase, will cause a direct negative impact on the benthos of local extent, short-term, reversible, repeatable during the construction period, of medium intensity.

Given the short-term exposure of benthos to elevated suspended solids in the farm area and buffer zone and the insignificant magnitude of the process, the significance of the described impact will be negligible for this group of organisms.

An assessment of the significance of this impact for the most far-reaching NIS 2015 scenario, which formed the basis for conducting the assessment for the Project under the parameters approved by the Environmental Decision, is presented in Table 15 below.

As a result of the modification of the Project's parameters, fewer foundations will be built than provided for in the set of parameters constituting the 2015 NIS, as well as in the parameters approved by the Environmental Decision, nevertheless, one maximum value of suspended solids concentration above the bottom will be the same as in the case described by the NIS. The effect of slurry spreading depends most on the conduct of the power plant foundation installation processes themselves, however, given the reduction in the number of power plant installation operations by 70% compared to the parameters constituting the NIS, as well as the exclusion of the use of gravity foundations in the case of the power plant, both the total time associated with sediment disturbance activities and the spatial extent of interference will be significantly reduced, and thus, it should be recognized, will be less than that occurring with the parameters of the Project approved by the Environmental Decision. Thus, it is considered that the impacts on benthos caused by the Project under the revised parameters will be less than those caused by the Project under the parameters approved by the Environmental Decision.

Table 15. Assessment of impact on benthos by increasing suspended solids concentration in water (construction phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Phytobenthos	Small	Low or medium	During the construction of the farm, the structure of the bottom sediments will be disturbed, leading to an increase in the concentration of suspended solids in the water	Negligible (scale of exposure - local, duration - short term, intensity - medium)	Negligible (magnitude of impact - insignificant, importance of the resource - low)
Macrozoobenthos	Medium	None, very low or low		Negligible (scale of exposure - local, duration - short term, intensity - medium)	Negligible (magnitude of impact - insignificant, Importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015.

Thus, it should be considered that both the nature of the impacts, as well as their scope and magnitude will not change in relation to the Project in the parameters approved by the Environmental Decision, and thus the change in the parameters of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.1.3. Deposition of suspended solids on the seabed sea

As a direct result of the disturbance of the bottom sediment structure, suspended solids will rise and spread (resuspension) in the water depths, and be re-deposited on the bottom.

The suspended solids stirred up during construction activities will re-deposit on the seabed after a while. The figures below show the area over which sediment will fall after construction for the project alternatives considered in the 2015 Report.

In the process of sedimentation in the area and vicinity of OWF BIII, the habitat of benthic organisms may be covered with 2 - 3.5 mm of additional sediment layer (Lech-Surowiec et al. 2015), which is a relatively low value. Modeling indicates that some of the suspended solids are carried with currents away from the study area, where sedimentation will occur after foundation and cable foundation work is completed in the seabed. The range of sedimented suspended solids will extend beyond the farm's boundaries to about 20 km to the northwest and southwest (a small section of the bottom of the Slupsk Shoal), but the thickness of the deposited sediment may be as little as 0.4 mm, a value that is practically difficult to detect and insignificant in terms of impact on the physiology of benthic organisms (Lech-Surowiec et al. 2015).

A model of suspended solids spreading, along with a full discussion of the process, can be found in Chapter 11 of Volume II of the report.

The sensitivity of **phytobenthos** to sedimenting suspended solids is medium to low (Table 11). This sensitivity is due to the life history strategy of the taxon in question. Carnivores are among the perennial

taxa whose growth is slow and population recovery takes up to 5 years. In addition, they exhibit only two types of asexual reproduction - mold fragmentation and spore production. Filamentous brine shrimp complete their life cycle in one year. During its course, they reproduce intensively using a variety of asexual and sexual reproduction methods. If backfilled with suspended solids, there should be no greater disturbance of the qualitative and quantitative structure of macroalgae than those that naturally occur in the environment (action of bottom currents, storms). Thus, it should be concluded that the significance of the impact of the backfilling of organisms with sedimentary suspension on phytobenthos is negligible.

The sensitivity of macrozoobenthic organisms additionally covered by up to 5 cm of sediment for a month is basically low (Berglund 2009), as in the mussel Mytilus trossulus characteristic of one of the distinguished assemblages.

In the second assemblage, *Pygospio elegans*, vagile infauna species (polychaetes) have the ability to burrow away, *crustaceans* to escape, and bivalves to project long siphons above an additional layer of sediment. In this assemblage, dominated in terms of biomass by the Baltic hornwort *Macoma balthica*, most populations of this species having a long siphon can survive for a month with a 7 cm increase in the sedimentary suspension layer (Turk and Risk 1991). Only the sensitivity of the common serpentine *Cerastoderma glaucum* is high, as this species has short siphons and does not tolerate admixtures of silt and organic matter on the surface of bottom sediments. In the case of the studied region of OWF BIII, the share of *Cerastoderma glaucum* in the *Pygospio elegans* assemblage did not exceed 22% in terms of biomass (Figure 5.12. in Blenski et al. 2014). Other literature data indicate that shallow-burrowed organisms feeding by filtration, especially juveniles, can survive even covered by an additional layer of sediment up to 50 cm thick (Hiscock et al. 2002).

The low sensitivity of backfilling the bottom fauna with an additional layer of sediment, up to a maximum of 3.5 mm, determines the insignificant magnitude of this process. In the case described, due to the local and short-term degree of impact, the overall significance of the impact of sedimentation on macrozoobenthos will be negligible.

Given that even in the most far-reaching scenario - NIS 2015, the significance of the impact at the OWF construction stage on the benthos was assessed as negligible, minimization measures are not required.

The deposition of agitated sediment on the seafloor, resulting from previous disturbance of the bottom sediment structure and suspended solids spreading during the construction phase, will cause direct negative impacts on the benthos of local extent, short-term, reversible, repeatable during the construction period, with low intensity.

An assessment of the significance of this impact for the furthest-reaching NIS 2015 scenario, which formed the basis for conducting the assessment for the Project under the parameters approved by the Environmental Decision, is presented in Table 16.

In the case of updating the parameters of the Project, fewer foundations will be placed than envisaged for both the 2015 NIS (about 70% less) and the parameters approved by the Environmental Decision (about 50% less) in addition, the possibility of using gravity foundations for power plant foundations will be excluded, while the number of foundations for related infrastructure - substations - will be reduced from 6 to 1 unit. The pointwise occurring maximum values of the additional sediment layer are lower for the modified parameters of the Project both against the 2015 NIS and for the Project under the conditions approved by the Environmental Decision. Suspended sedimentation sites will also cover a smaller area. The Project under the updated parameters will result in lower impacts on benthos from both the 2015 NIS and the Project under the conditions approved by the Environmental Decision.

Table 16. Assessment of the impact on benthos of suspended solids deposition on the seabed (construction phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Phytobenthos	Small	Low or medium	During the construction of the farm, the structure of the bottom sediments will be disturbed, leading to an increase in the concentration of suspended solids in the water and their subsequent redeposition on the seabed	Negligible (scale of exposure - local, duration - short-term, intensity - low)	Negligible (magnitude of impact - insignificant, importance of the resource - low)
Macrozoobenthos	Medium	None, low or medium		Negligible (scale of exposure - local, duration - short-term, intensity - low)	Negligible (magnitude of impact - insignificant, importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015.

Thus, it should be considered that both the nature of the impacts does not change, and their scope and magnitude are smaller than in the case of the variant approved by the decision, and thus the change in the parameters of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings in the course of which the Environmental Decision was obtained.

9.1.4. Release of pollutants and nutrients from the sludge into the water body water

Agitation of the bottom sediment associated with foundation placement for farm facilities, ship anchoring or cable burial is a process that promotes the passage of contaminants from the sediment to the water depths (Frostner, 1980; Bourg and Loch, 1995; Bojakowska, 2001; Dembska, 2003; Uścinowicz, 2011). This way they can get to it:

- pollutants, including heavy metals and PAHs and PCBs,
- biogenic elements - nitrogen and phosphorus.

This process is described in detail in Chapter 9.1.2 of the assessment of the impact of OWF BIII on the abiotic environment (Volume IV Section 2 of the EIA). During the construction of the farm, some amounts of heavy metals, persistent organic pollutants and phosphorus (biogen) will be released into the water depths, which, however, will be small compared to the load carried into the Baltic Sea with rivers and wet precipitation (cf.: abiotic environmental impact assessment - Volume IV Section 2 of the report, Chapter 9.1.2.).

Phosphorus, the content of which in the analyzed sediments from the BIII offshore wind farm area did not exceed values typical of Baltic Sea sediments (Dembska et al., 2015 - Volume III Section 5 of the report), is not expected to have an impact on limiting the development and occurrence of phytobenthos.

Bivalves can accumulate harmful and toxic substances: heavy metals and pesticides (Herra and Wiktor, 1985; Szaniawska, 1991). High concentrations of heavy metals can be toxic to aquatic plants (Lobban

and Harrison, 1997), leading, among other things, to a reduction in photosynthesis (Baumann et al., 2009). In the area of the planned location of OWF BIII, concentrations of persistent organic pollutants (i.e., PAHs, PCBs) and harmful substances, such as heavy metals and mineral oils, occurred at low levels and did not exceed values typical of sandy sediments of the southern Baltic Sea (Dembska et al., 2015 - Volume III Section 5 of the report). Also, the content of tributyltin (TBT) in the studied sediment from the BIII offshore wind farm area occurred at levels below 0.01 $^{mg\text{-}kg\text{-}1}$ s.m. (Dembska et al., 2015 - Volume III Section 5 of the report). These concentrations were typical of sandy sediments in the southern Baltic Sea (HELCOM 2002).

The release of pollutants and nutrients from the sediment into the water body, resulting from previous disturbance of the bottom sediment structure during the construction phase, is a direct, negative, local in scope, short-term, reversible, repetitive impact during the construction period, with high intensity.

Both for the set of parameters of the Project constituting the 2015 NIS, as well as for the parameters of the Project approved by the Environmental Decision, the possible impact of the released harmful substances and phosphorus from the sediments during the installation of foundations and the laying of internal cables in the seabed on the benthos will be insignificant, as the significance of this impact is negligible or small depending on the importance of the different benthic groups being assessed. **Consequently, the proposed changes to the Project will also be negligible, and minimization measures are not required.**

An assessment of the significance of this impact **for the most far-reaching NIS 2015 scenario,** is presented in Table 17 **below.**

In the case of updating the parameters of the Project, fewer foundations will be laid than envisaged in the NIS 2015, as well as than in the parameters of the Project approved by the Environmental Decision, moreover, the possibility of using gravity foundations for power plant foundations has been excluded, while the number of foundations for related infrastructure - substations - has been reduced from 6 to 1 unit, allowing to consider that the Project in the updated parameters will not cause impacts on benthos on a scale exceeding those caused by the parameters of the Project approved in the Environmental Decision.

Table 17. Assessment of impacts on benthos of released pollutants and nutrients (construction phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Phytobenthos	Small	Low or medium	During the construction of the farm, the bottom sediment structure will be disturbed, leading to the release of pollutants and nutrients from the sediment into the water body, which may affect the benthos	Negligible (scale of exposure - local, duration - short term, intensity - medium)	Negligible (magnitude of impact - insignificant, importance of the resource - low)
Macrozoobenthos	Medium	None, low or medium		Negligible (scale of exposure - local, duration - short term, intensity - medium)	Negligible (magnitude of impact - insignificant, importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015.

Thus, it should be considered that both the nature of the impacts remains unchanged, and their scope and magnitude are smaller than in the case of the variant approved by the Environmental Decision, and thus the updating of the parameters of the Project does not affect the result of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.1.5. Impact cumulative

Assumptions for analyses of cumulative impacts for the change of the Project - OWF BIII and other projects on benthos are presented in Chapter 3.2. An extensive description regarding this issue is provided in Section 13 of Volume II of the EIA.

At the stage of construction of the BIII offshore wind farm, cumulative impacts may arise if installation work on several offshore wind farms proceeds simultaneously, including foundation placement, as well as as as a result of dredging the bottom for internal and external connection infrastructure cables installed in it. Cumulative impacts involve investments located close to each other.

In the case of the BIII offshore wind farm, it will be adjacent to the Baltic offshore wind farm.

In any case, a potential type of impact that could negatively affect the benthic communities of OWF BIII is the agitation of bottom sediments leading to an increase in suspended solids in the water depths and the process of covering organisms with an additional layer of sediment during the sedimentation of suspended solids.

The impact assessment conducted in the 2015 Report assumed two possible scenarios for cumulative impacts affecting the physiology and survival of the BIII OWF benthos:

The first of these assumed that in 2019 - 2021 for the built power plants with a total capacity of 900 MW, including 600 MW under the BIII offshore wind farm and 300 MW under the Baltica 3 offshore wind farm. Assuming an average power plant of 6 MW, 150 will be built. Associated infrastructure (e.g., substations, additional platforms, such as social) will also be built. It can be assumed that 158 foundations and about 158 km of internal cables will be installed on the seabed in this connection.

To these 2 farms, onshore export cables will be built with an estimated length of 95 km and 45 km, respectively. However, export cables will be built only for very short distances near the farm, and then, as they approach the shore - at a distance that causes no or negligible accumulation. In 2019-2021, geotechnical drilling may also take place in the areas of the Gaz South and Slupsk E concessions, but these impacts should also be considered negligible, due to the vastness of the concession areas and only minor overlaps with the areas of wind farms planned in the area. Export cables and geotechnical surveys in hydrocarbon concession areas were therefore not taken into account in further cumulative impact analyses.

In addition, there is a heavily used shipping route (*Traffic Separation Scheme* (TSS)) near the farm, in the area of which there is an increased risk of oil spills.

Some simplifications have been adopted due to the fact that no environmental studies have been carried out for the Baltica 3 offshore wind farm project at that time, and therefore it has been assumed that the environmental conditions will be similar to those at the BIII offshore wind farm, it has been considered that in the above scenario the level of cumulative impacts on benthos will be only 75% of the level analyzed in the report as NIS 2015.

It was also assumed that more power plants will be built between 2023 and 2026, with a total capacity of 1,350 MW, including 600 MW under OWF BIII and 750 MW under OWF Baltica 3. Assuming an average power plant of 6 MW, 225 will be built. Associated infrastructure (e.g., substations, additional

platforms, such as social) will also be built. It was assumed that 232 foundations and about 232 km of internal cables would be installed on the seabed in this connection.

A different **scenario** for the construction phase, assumes that the above numbers of power plants and associated infrastructure elements will be built not in the areas of OWF BIII and OWF Baltica 3, but as OWF **BII and OWF Baltica 2** (PSZWs belong to the same owners). However, such an alternative scenario did not significantly change the level of impacts.

According to the analyzed scenarios, it was estimated that the **level of cumulative impacts on benthos would be only 16.5% higher, from the level analyzed in the report as NIS 2015. And as a result, the impact significance assessment, for such a construction phase scenario, was found to be no different from the impact assessment presented in Chapter 9 for the 2015 NIS and the rational alternative and the BIII offshore wind farm variant.**

In doing so, it should be noted that most of the impacts described in Section 9.1 will not be cumulative, due to the scope being limited to the site of the foundation in question or its immediate vicinity.

Compared to the assumptions of the scenarios adopted in the 2015 Report, the timing of all planned projects has changed, and they have all been delayed.

In addition, an environmental decision has been issued for the Baltic Power MEW project. The environmental impact report for the Baltic Power MEW project shows that the exact timetable for the project is not known. However, even in the case of a situation of parallel execution of the BIII OWF project and the Baltic Power OWE, in the case of execution of the Project in the proposed modified parameters, there will be no more far-reaching impacts than those assessed in the proceedings during which the Environmental Decision was issued. The Baltic Power FEW Baltic II project involves the construction of 126 wind power plants. In contrast, the BIII OWF in its planned modified parameters assumes the construction of 60 wind turbines, which represents 30% of the wind turbines evaluated in the 2015 NIS, which is the basis of the BIII OWF benthic impact assessment. In addition, the modified parameters of the Project assume the abandonment of the possibility of gravity and tripod foundations, i.e. the solutions with the greatest significance from the point of view of the impacts of potential impacts on benthos. By the same token, it should be considered that the impacts caused by the implementation of the projects included in the scenarios forming the basis of the analyses adopted in the 2015 Report will not increase in the event of implementation of the Project in the proposed modified parameters, and the scenarios themselves can be considered valid for making inferences about cumulative impacts.

A summary of cumulative impacts during the construction phase of the BIII OWF is presented in Table 18 below.

Table 18 Assessment of the cumulative impact of the project on benthos during the construction phase regardless of the project variant - NIS 2015, variant approved by the Environmental Decision

Cumulative impacts on benthos	The significance of the impact	
	Phytobenthos	Macrozoobenthos
Disruption of sediment structure	No change	Small
Increase in the concentration of suspended solids in water	Skip	Skip
Deposition of agitated sediment	Skip	Skip

9.2. Stage operation

During the operation of OWF BIII, works affecting the seabed and seawater will be carried out in its area, mainly maintenance works. Among other things, their effect will be a slight disturbance of the sludge structure, causing further release of pollutants and nutrients from the sludge.

A full description of the work during the operation stage is provided in Chapter 5 of Volume II of the EIA.

The benthos will be impacted at the operational stage primarily by foundation structures that will occupy part of the seabed, leading to the loss of its habitat. During the operation of the OWF, benthic organisms will repopulate the degraded bottom area in the vicinity of the foundations and cables. Presumably, in places where sediment of a different granularity than the original one has been exposed, the newly formed macrozoobenthos assemblages will have a different structure than before the construction of the farm.

The following impacts of OWF BIII on benthos are expected to occur at the operational stage:

1) seabed area occupation,
2) the creation of an "artificial reef."
3) contamination of the water tone and sediments with anti-corrosive agents,
4) changing water and sediment temperatures,
5) changing the regime of sea currents,
6) wind wave attenuation.

There may also be unplanned impacts during the operation of the farm, particularly pollution of the water table and bottom sediments:

1) petroleum substances,
2) antifouling agents,
3) accidentally released municipal waste or domestic sewage,
4) accidentally released chemicals and waste from the operation of the farm, which may indirectly affect the benthos.

Unplanned impacts are assessed in Chapter 11.

9.2.1. Occupation of the seabed area

The foundation of the foundations, along with the seabed leaching protection layer, will result in the occupation of the seabed area, and thus the complete loss of the natural benthic habitat at the site, which will last for the entire period of operation.

As already indicated in Section 9.1.1, in the most far-reaching scenario that may occur in the rational alternative, i.e. in connection with the construction of 208 foundations, they will occupy, including cables, about 1.1 ^{km2} or about 1.12% of the farm's area. In the variant approved by the Environmental Decision, the number of foundations will be about 40% lower (maximum 126 units), while the length of cables will remain unchanged, and in the case of the variant after conducting the proposed changes, the number of foundations will be about 70% lower (maximum 61 units) compared to the parameters of the Project constituting the 2015 NIS.

In the area occupied by the foundations, there will be a complete loss of macrozoobenthos habitat, which will continue throughout the operation period, and if the foundations are not subsequently removed, even after the decommissioning of the farm. Phytobenthos was only recorded in the buffer zone of the farm during environmental surveys.

A similar loss of habitat will occur as a result of the leaching protection layer. This is because the sub-fractional composition of the bottom sediments will change here (cf. Abiotic Environmental Impact Assessments, Volume IV Chapter 2 of the EIA). For this purpose, rock ballast, stones and boulders are usually used, with which the base of the foundation is surrounded by a width of several to several meters. Environmentally neutral materials are used. The appearance of coarse rock crumbs can contribute to the creation of new habitats for sessile benthos.

The sensitivity of benthos to habitat loss is low only for crustaceans - Crustacea due to their mobility. Other organisms have medium sensitivity.

It should be noted that as a result of the change in the parameters of the Project, fewer foundations will be placed than envisioned for both the NIS (about 70% less) and the parameters approved by the Environmental Decision (about 50% less). In addition, with regard to power plant foundations, the choice of foundation type was limited to monopile and jacket type, abandoning tripod and gravity type foundations for which the area where permanent loss of benthic habitat occurs is the largest. Consequently, minimization measures are also not required.

Habitat loss is a direct, negative impact on the benthos of OWF BIII of local scope, long-term, irreversible, permanent, with very high intensity.

An assessment of the significance of this impact for the furthest-reaching NIS 2015 scenario underlying the assessment in the 2015 Report is presented in Table 19 below.

If the parameters of the Project are updated, fewer foundations will be placed than envisaged for the parameters of the Project approved in the Environmental Decision and the 2015 NIS, and the use of gravity and tripod foundations has been ruled out; consequently, habitat loss will occur over a smaller area. For the above reasons, it should be considered that the Project in the updated parameters will cause significantly lower impacts on benthos compared to the set of parameters of the Project constituting the 2015 NIS, as well as the Project in the parameters approved by the Environmental Decision.

Table 19. Impact assessment of benthic habitat loss (operational phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Phytobenthos	small	Low	During the operation of the farm, there will be a loss of benthic habitat due to the occupation of the seabed area by foundations	No change (no loss of the resource, no impact on the structure and operation of the resource)	No change (magnitude of impact - no change, importance of the resource - low)
Macrozoobenthos	average	Low or medium		Moderate (scale of exposure - local, duration - long-term, intensity - very high)	Small (magnitude of impact - moderate, importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015.

Thus, it should be considered that both the nature of the impacts remains unchanged and their scope and magnitude are smaller than in the case of the variant approved by the Environmental Decision, and thus the update of the Parameters of the project does not affect the result of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.2.2. The creation of an "artificial reef"

Taking into account the significant reproductive potential of benthic bottom communities, the great adaptability of most of the species included in them, we should expect rapid colonization of the artificial substrate introduced into the environment, namely the surface of the underwater structure of wind turbines and the scour protection layer built of rocks and boulders. There will be a localized long-term colonization of the new hard substrate by animal and plant assemblages of epiphytes, followed by mobile epifauna.

Exemplary monitoring of the "artificial reef" effect from the operating Nysted OWF (Baltic Sea, Denmark) indicates that one year after the farm was put into operation, the first colonizers on underwater elements were barnacles*(Balanus improvisus*) and small individuals of mussels*(Mytilus edulis*) with shell lengths of less than 10 mm. Deeper than them, an increase in mobile crustaceans was observed: *Corophium insidiosum,* Microdeutopus sp. and the appearance of the crab *Carcinus maeans*. Among the phytobenthos, brown algae dominated, crayfish reached sizes larger than average, and green algae were rare (Birklund and Petersen, 2004). On the foundations of the operating Horns Rev offshore wind farms in the North Sea (Denmark), aggregations of the mussel *Mytilus edulis* dominated, making up 90% of the macrozoobenthos biomass on all monopiles as early as the third year of the farm's operation (Langhamer et al., 2009). An experiment conducted in the waters of the Baltic Sea (the Bay of Puck) on an artificially introduced structure, made it possible to observe the phenomenon of its overgrowth by plant and animal epiphytic organisms. Two sessile species stood out among the dominants: barnacles *Balanus improvisus* and mussels *Mytuilus trossulus*, which overgrew the structures first, followed by periwinkles, crustaceans, bryozoans, green algae and the brown alga *Pylaiella littoralis*. The proportion of barnacles and mussels on the structure decreased with depth (Dziubinska and Szaniawska, 2010).

It is not possible to predict a clear-cut scenario of what the colonization of the artificial substrate will actually look like. It is presumed that in the Baltic waters of the BIII OWF area, the dominant species of epiphytic fauna will mainly include the mussel *Mytilus trossulus*, barnacles *Balanus improvisus* and several species of phytophilous fauna (crustaceans: Gammarus sp., *Corophium volutator* or *Monoporeia affinis*). Macrozoobenthos colonization will occur when the larvae, after a period of reproduction that usually takes place in late spring, settle on structural elements and the bottom, and develop into adult forms. Recovery of the qualitative state (species composition) will occur no later than one year after the species' breeding period, while recovery of the quantitative state will occur after the mussel reaches its maximum size and biomass (about 5 years) (Vuorinen et al., 2002).

The ant flora will be most abundant during the initial phase of colonization, and its presence depends on depth and light availability. There will be a new refuge for juvenile fish and an attractive feeding, spawning and sheltering area for many fish species, as well as a food base for birds. Clams will also overgrow the stones surrounding the base of the foundation, and the spaces between the boulders can be used as shelter for small fish. The appearance of the "artificial reef" will partially compensate for the loss of damaged bottom assemblages. The role of mussels as biofiltrators in polluted and zeutrophicated waters is well known. Absorbing the suspended solids of the water tone, through their ability to agglutinate and excrete them in the form of fecal and pseudofecal matter, they contribute to the

purification of the reservoir, accelerate the sedimentation of suspended solids, enriching the bottom with detritus (biosolids) and organic matter. They can also accumulate harmful and toxic substances: heavy metals and pesticides (Herra and Wiktor, 1985; Szaniawska, 1991), but their concentration in the project area sediment is very low. The fecal and pseudo-fecal matter intensively produced by the mussels as they sink to the bottom will change the trophic state of the surface layer of bottom sediments, but will be partly carried with the currents out of the "artificial reef" habitat area.

Artificial substrate, which will appear even at a considerable distance from land, can be colonized by species of macroalgae, whose spores, along with currents, will reach the site of the wind farm. These may be organisms that would never appear in the area due to the considerable depths limiting their occurrence, such as green algae that prevail on hard substrate in the coastal zone to a depth of several meters. The development of macroalgae along with mussels and barnacles is observed on the concrete foundations of wind farm turbines and transformer stations (Roth et al., 2004).

In wind farms operating in Denmark, the new area of the farm's underwater structures was as much as 1.5 times larger than the area of the sand bed habitat destroyed at the site (Birklund, 2009). At the Nysted Offshore Wind Farm in the western part of the Baltic Sea, 5 years after the foundations had been laid, the biomass of the epiphytic organisms was 20 times higher than the biomass of the benthos (mainly infauna) of the sandy bottom that had been destroyed at the site (Leonhard, 2006).

Taking into account several assumptions, it is possible to calculate by how much the area of the hard bottom will change in the BIII OWF area. The natural hard bottom (gravel, pebbles) is located in the northwestern part of the BIII OWF proper and buffer zone (36.9 ^{km2}, about 20% of the total area of the farm), where the mussel *Mytilus trossulus* dominates in abundance and biomass (Bleńska et al. 2014). Assuming that the radius of the underwater part of the wind turbine pile above the foundation will be 5 m, and its height is 30 m, the area possible for the overgrowth of these structures by fauna and partly flora (up to 20 m deep) of epiphytes will be 943^{m2}. On the other hand, the area of the leaching protection layer around one pile (with a width of 15 m) possible for colonization will be 2591^{m2}, which gives a total of 0.0035 ^{km2} including the pile area. The area of loss of habitat and macrozoobenthos assemblage under a single foundation including the leaching protection layer is 0.0038 ^{km2}. This means that the surface area of the hard artificial substrate of underwater wind turbine structures is almost the same as that of the degraded natural environment. For the most far-reaching scenario (NIS), which may occur in the rational alternative, i.e. in connection with the construction of 208 underwater wind turbine structures and associated infrastructure, the new area of artificial hard substrate will be 0.728 ^{km2} (0.8% of the farm area).What is important from the point of view of the food base for bentophages is that the habitat-forming mussels that will be destroyed under the gravity foundations along with the leaching protection layer will be able to colonize the hard substrate of the underwater wind turbine structures with an area comparable to the area of the bottom destroyed by the foundation and stone protection layer. However, it is difficult to predict what the total biomass of the epiphytic fauna will be, as there have been no wind farm construction, operation or dismantling activities in the South Baltic, let alone monitoring of the "artificial reef" phenomenon. The closest operating offshore wind farms to the BIII offshore wind farm area are located in the Danish Straits. However, it is not valid to compare or use monitoring data on the biomass of biota from that area. For example, the average salinity of the waters of the Fehmarnbelt, where the Nysted Offshore Wind Farm (with a maximum height of underwater structures of up to 10 meters) is located (Birklund and Petersen 2004), is 15-23 PSU (Feistel et al. 2005). Under such conditions, the same species of mussel *Mytilus trossulus* reaches a large larger size and biomass than in the South Baltic, and the composition of the entire biota is much more diverse.

Although the phenomenon associated with the creation of the "artificial reef" is long-term and of very high intensity, its local scope ultimately affects the low significance of this impact. Moreover, the nature of the impact is difficult to determine clearly. On the one hand, the effect of the "artificial reef" will locally increase species diversity and biological production, especially in the context of a new food base for fish and birds, and this determines the importance of the habitat for the course of ecological

processes. On the other hand, any interference in the environment that destroys its naturalness makes such an impact take on a negative character with unknown effects on the ecosystem in the long term.

The "artificial reef" effect promotes the possibility of alien or invasive species becoming established due to favorable feeding and breeding conditions at the BIII OWF foundation site, which is a negative effect on preserving the naturalness of the local micro-ecosystem. The POM recorded 30 non-native species belonging to the following groups: phytoplankton, zooplankton, macrophytes, zoobenthos and avifauna, and 26 species of ichthyofauna. The highest number of alien species has been recorded in the Polish coastal zone of the Gulf of Gdansk (Krzymiński, 2013). Among the benthos, crustaceans account for the largest number of alien species, which can quickly displace native species leading to a change in the existing balance in the trophic network of the ecosystem. In the POM, 11 of the 56 crustacean species are alien species (Jażdżewski et al., 2005). Most of them, such as obunogs, are native to the Ponto-Caspian region (Black Sea, Caspian Sea, Sea of Azov). Others were brought from the Atlantic Ocean, and the crab *Eriocheir sinensis* from as far away as eastern Asia (Grabowski et al, 2005; Jażdżewski et al, 2005; Ovcarenko et al, 2006). The alien species *Palaemon elegans* is an excellent colonizer and shows a wide tolerance to colonize a variety of habitats. *P. elegans* is displacing the native species *P. adspersus* and has become a permanent part of the Baltic fauna (Grabowski, 2006). Most of the amphipods "foreign" to the Baltic get here from the Ponto-Caspian area, and they may be transported in ballast water from the Atlantic coast of North America (Jażdżewski et al. 2002).

Despite the small area of loss of natural habitat in OWF BIII, the effect of the "artificial reef" will make the natural valuation of the project area different from the state before human interference with the environment.

The formation of an "artificial reef" is a direct impact on the ecosystem of the BIII OWF of local scope, long-term, irreversible, permanent, with very high intensity. It should be noted, however, that in this case, the original assemblage of benthic communities of the BIII offshore wind farm area is no longer subject to assessment, but the biota. In the case of the "artificial reef" effect, the existing benthic community of OWF BIII is no longer evaluated, but only the scale, intensity and magnitude of the phenomenon can be assessed. Full information taking into account the qualitative-quantitative specifics of the "artificial reef" effect in the BIII OWF area will be provided by monitoring.

An assessment of the significance of this impact **for the set of parameters of the Project constituting the most far-reaching scenario, the 2015 NIS,** is presented in Table 20 below.

Updating the parameters of the Project means that fewer foundations will be built than envisioned in the parameters of the Project set forth in the Environmental Decision and fewer than in the 2015 NIS, thus the effect of the "artificial reef" in the context of the new artificial foundation on the pile support structures will be correspondingly less. It is considered that the Project in the modified parameters will cause less impact on the BIII OWF ecosystem than the Project in the parameters approved by the Environmental Decision and the 2015 NIS.

Table 20. Impact of the "artificial reef" on the BIII offshore wind farm ecosystem (operational phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Phytobenthos	Small	Average	An "artificial reef" will be built on the exploited foundations	Moderate (scale of exposure - local, duration - long term, intensity - very high)	Small (magnitude of impact - moderate, importance of the resource - low)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Macrozoobenthos	Medium	Average		Moderate (scale of exposure - local, duration - long-term, intensity - very high)	Small (magnitude of impact - moderate, importance of the resource - medium)

9.2.3. Contamination of the water tone and bottom sediments with compounds from corrosion protection agents

Steel structures of power plant and substation foundations will corrode in the marine environment. Accordingly, appropriate protective measures will be necessary. The most common anti-corrosion method used in the marine environment is cathodic protection. It can be implemented as galvanic or electrolytic protection.

Galvanic cathodic protection involves installing aluminum or zinc anodes on the foundations. The anodes are gradually consumed, and Al or Zn passes into the water depths and accumulates in the bottom sediments. In the case of electrolytic protection, such interactions do not occur. Thus, the assessment applies only to galvanic cathodic protection.

This impact is described in detail in Section 9.2.10 of the abiotic impact assessment (Volume IV Chapter 2 of the EIA).

Projected amounts of Zn or Al per foundation during the entire operation of the farm and per farm per year are presented in Chapter 2 of Volume IV of the Report. The most far-reaching scenario is the installation of monopiles rather than gravity foundations. According to the information presented in the aforementioned chapter, during the 25 years of operation of the BIII OWF in the 2015 NIS, only 5.36 tons of Zn will pass into the environment annually. This is not much compared to the approximately 700 tons of Zn discharged into the Baltic Sea annually by rivers from Poland, but the above amounts, when released into the water's depths or accumulating in bottom sediments, can affect the benthos. However, this will be an impact at the threshold of detection.

In the currently requested variant, there has been a reduction in the total number of foundations.In this variant, only monopile and jacket foundations can be used in the Project for the installation of wind turbines. If galvanic cathodic protection is used, reducing the number of BIII OWF foundations, as well as excluding tripod-type foundations (which potentially require the largest number of anodes) from further consideration for wind power plant siting, will reduce the total amount of anode material required, and thus emissions to the marine environment. The impact in this regard will therefore remain insignificant.

In summary, the variant that is the subject of this Report will build about 70% fewer foundations than envisioned for the furthest-reaching scenario that forms the basis of the assessment in the 2015 Report - NIS 2015, and twice as many as specified in the Environmental Decision, which also entails the use of a correspondingly smaller number of anodes for corrosion protection, and thus fewer emissions. The calculations presented showed that with the application of an additional protective coating of the amounts of Zn and Al, additional reductions in the elements released into the environment will be achieved, and thus the project will cause lower impacts both from the Project in the parameters constituting the NIS and from the variant approved in the Environmental Decision.

Table 21 Assessment of the impact on benthos from contamination of water bodies and bottom sediments with compounds from corrosion protection agents (operational phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Phytobenthos	Small	Very low	During the operation of the foundations, corrosion protection measures will be applied, which involves Zn or Al emissions and which may affect the benthos	No change (no loss of the resource, no impact on the structure and operation of the resource)	No change (magnitude of impact - no change, importance of the resource - low)
Macrozoobenthos	Medium	Very low		No change (no loss of the resource, no impact on the structure and operation of the resource)	No change (magnitude of impact - no change, importance of the resource - medium)

Thus, it should be considered that both the nature of the impacts does not change and their scope and intensity are smaller than in the case of the variant approved by the Environmental Decision, and thus the proposed change in the parameters of implementation and operation of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.2.4. Change in temperature of water and sediments

Electric current, flowing through the power cable, causes it to heat up, caused by power losses on the resistance, according to Joule's law. With the increase in cable temperature above ambient temperature, heat transfer to the surrounding environment begins. This impact is described in detail in Section 9.2.11 of the abiotic impact assessment (Volume IV Section 2 of the EIA).

For example, in the operating Nysted Offshore Wind Farm, the temperature rise emitted by a transmission cable (132 kV) buried at a depth of 1 m, did not exceed 1.4oC in the layer 20 cm above the cable, and already at the surface of the bottom the temperature changes were invisible (Merck, 2009). The cable was buried in gravelly sediment, which promotes much greater heat loss in the interstitial spaces between sediment grains than in fine-grained sediment (Merck, 2009). Both of these sediment types are common in the area of the planned BIII OWF. It should be assumed that the heat dissipation (24 W/h/m on the cable surface) emitted by the internal 33 or 66 kV cables belonging to OWF BIII will be less (or at most similar) to that recorded at the Nysted offshore wind farm.

Heating the bottom sediment and interstitial waters (waters that fill the spaces between sand grains in the sediment) can also promote the passage of metals from the sediment to the water table and accelerate the decomposition processes of organic contaminants in the bottom sediment. In general, benthic fauna are naturally adapted to large seasonal temperature changes and are not sensitive or show very low sensitivity to a 2°C (2 K) temperature increase (Birklund, 2009). According to standards proposed by the German Federal Agency for Nature Conservation, the temperature rise due to the heat emission of an offshore wind farm transmission cable in the 20 cm layer below the bottom surface, which is the main habitat for infauna, must not exceed 2 K (2°C). Heat emission over the OWF BIII cables in the settlement will be local and the effect will be imperceptible if the cable is buried deeper than 1

m, while internal power cables are to be buried at a depth of 3 m. **Therefore, no impact of this parameter on the benthos is expected. Minimization measures are not required.**

The cable's thermal emissions will not have an impact on the structure and functioning of the benthos in the project area both for the set of parameters of the Project constituting the 2015 NIS and in the parameters approved by the Environmental Decision, as shown in Table 22 below .

Table 22 Assessment of impact on benthos by changing water and sediment temperature (operational phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Phytobenthos	Small	Very low	Operated power cables will emit heat, which may affect benthos	No change (no loss of the resource, no impact on the structure and operation of the resource)	No change (magnitude of impact - no change, importance of the resource - low)
Macrozoobenthos	Medium	Very low		No change (no loss of the resource, no impact on the structure and operation of the resource)	No change (magnitude of impact - no change, importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015.

As a result of updating the parameters of the Project, the maximum length of the cables of the internal connection infrastructure of the farm will not change compared to the parameters approved by the Environmental Decision, thus it should be considered that the impacts generated by the Project in the modified parameters will not be of a different nature, scope or magnitude. Thus, the update of the Parameters of the project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.2.5. Changes in the regime of currents seas

The foundation of gravity foundations disturbs the processes of water hydrodynamics, especially the flow of sea currents over the bottom, leading to changes in the granulometry of the upper sediment layer, increased bottom erosion and sedimentation processes. This impact is described in detail in Section 9.1.10 of the abiotic impact assessment (Volume IV Section 2 of the EIA).

Hydrological studies in the area of OWF BIII show that an increase in current flow and reduced stratification of the water column will only occur in the immediate vicinity of the foundations. Rather, in the area of the farm (excluding the vicinity of the foundations), a decrease in the speed of currents is expected to be balanced by its increase outside the farm region (Lech-Surowiec 2015).

The sensitivity of most of the macrozoobenthos species found in OWF BIII to this type of impact is low with the exception of the bivalve Cerastoderma glaucum. In fact, the benthic fauna is adapted to the same but natural processes, so the magnitude and significance of the impact is small.

Changes in the regime of sea currents are indirect and negative impacts on the benthos of local extent, long-term, irreversible, repetitive, of medium intensity. Given that even for the set of parameters of the Project constituting the 2015 NIS, the significance of the impact on the benthos is negligible, small or moderate, minimization measures are not required.

An assessment of the significance of this impact for the furthest-reaching NIS 2015 scenario that forms the basis for conducting the assessment in the 2015 Report is presented in Table 23 below.

Hydrographic modeling shows that differences in the characteristics of the sea current regime between the project alternatives analyzed for the 2015 Report, resulting from the type and number of foundations placed (Lech-Surowiec et al. 2015 - Volume II Section 11 report), are very small. In the section on hydrographic modeling, this impact was assessed as negligible for both the 2015 NIS and the Project under the parameters approved by the Environmental Decision. Changing the parameters of the Project means changing the number of realized foundations, this allows one to consider oneself that the impacts of the Project after modification will not be greater than both the set of parameters of the Project constituting the NIS 2015 and the impacts caused by the Project in the parameters approved in the Environmental Decision.

Table 23. Assessment of the impact on benthos of changing the regime of sea currents through foundation structures (operational phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Phytobenthos	small	Small	Exploited foundation structures will cause a change in the regime of sea currents in the project area, which will indirectly affect the benthos	No change (no loss of the resource, no impact on the structure and operation of the resource)	No change (magnitude of impact - no change, importance of the resource - low)
Macrozoobenthos	average	Average		Small (scale of exposure - local, duration - long-term, intensity - medium)	Small (magnitude of impact - low, importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015.

Thus, it should be considered that both the nature of the impacts does not change, and their scope and magnitude are smaller than in the case of the variant approved by the decision, and thus the updating of the parameters of the Project does not affect the result of the environmental impact assessment carried out as part of the proceedings in the course of which the Environmental Decision was obtained.

9.2.6. Damping ripples

The foundation of gravity foundations will cause wave attenuation. When waves hit the foundation of a wind turbine, some of their energy is reflected. This causes wave changes inside the wind farm and in its leeward zone. This impact is described in detail in Section 9.1.14 of the abiotic impact assessment (Volume IV Section 2 of the EIA).

The impact will be the same as in the case of the impact on the change of sea currents.

Given that even for the set of parameters of the Project constituting the 2015 NIS, the significance of the impact on the benthos is negligible, small or moderate, minimization measures are not required.

Wave attenuation by foundation structures is an indirect, negative impact on benthos of local extent, long-term, irreversible, repetitive, of medium intensity.

An assessment of the significance of this impact for the most far-reaching scenario that could occur under the rational alternative is presented in Table

Changing the parameters of the Project means changing the number of realized foundations, decreasing the number of fudaewas means decreasing wave attenuation, which in turn makes it possible to consider that the impacts of the Project after modification will not be greater than both the set of parameters of the Project constituting the 2015 NIS and the impacts caused by the Project in the parameters approved in the Environmental Decision.

Table 24 Assessment of the impact on benthos of wave attenuation by foundation structures (operational phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Phytobenthos	Small	Small	Exploited foundation structures will cause a change in the regime of sea currents in the project area, which will indirectly affect the benthos	No change (no loss of the resource, no impact on the structure and operation of the resource)	No change (magnitude of impact - no change, importance of the resource - low)
Macrozoobenthos	Medium	Average		Small (scale of exposure - local, duration - long-term, intensity - medium)	Small (magnitude of impact - low, importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015.

Thus, it should be considered that both the nature of the impacts does not change, and their scope and magnitude are smaller than in the case of the variant approved by the decision, and thus the change in the parameters of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings in the course of which the Environmental Decision was obtained.

9.2.7. Impacts cumulative

The assessment carried out in the 2015 Report recognized that the possible cumulative impact at the stage of operation of the BIII OWF is related to the existence of other offshore wind farms in the vicinity of the BIII OWF, i.e., the BIII OWF. Baltica 3 offshore wind farm, Baltica 2 offshore wind farm, and BII offshore wind farm. It has been assumed that in 2021 - 2025, a total of 150 power plants with associated infrastructure will be operated under the BIII OWF and Baltica 3 OWF projects. While pointing out that in the above scenario, the level of cumulative impacts on abiotic environmental elements will be only 75% of the level analyzed in the report for the 2015 NIS.

It is also assumed that 225 more power plants will be built between 2023 and 2026, either within the framework of the OWF BIII and OWF Baltica 3 projects or, alternatively, on the surfaces of OWF BII and OWF Baltica 2. This would mean that as of 2026, a total of **375 power plants with infrastructure** will be in operation, in close proximity to each other, **i.e. 87.5% more than in the assessed 2015 NIS**, near the northeastern end of the Slupsk Shoal. **This was deemed not to affect the outcome of the evaluation.**

In doing so, it should be noted that most of the impacts described in Section 9.2 will not be cumulative, due to the scope being limited to the site of the foundation in question or its immediate vicinity.

In relation to the conditions related to the implementation of other OWF projects considered at the stage of the 2015 Report, a new circumstance is the fact that an environmental decision has been issued for the FEW Baltic II project and the Baltic Power OWF. The projects involve the construction of 44 and 126 wind power plants, respectively. In contrast, the BIII OWF in the updated parameters assumes the construction of 60 wind power plants, which is 50% of the number of plants envisaged by the Environmental Decision and 30% of those evaluated in the 2015 NIS. In addition, the modified parameters of the Project assume the abandonment of the possibility of gravity and tripod foundations, i.e. the solutions with the greatest significance from the point of view of the impacts of potential impacts on benthos. Consequently, updating the parameters of the Project offsets to some extent the impacts caused additionally by the planned OWF, thus contributing to the reduction of cumulative impacts that should be assessed in the environmental impact reports for the two projects.

Regardless of the scenario and the implementation of the Project in the parameters approved by the Environmental Decision, as well as in the case of the proposed modification of the Project, there will be an accumulation of "artificial reef" formation. A larger area of artificial ground than a single wind farm can develop a more diverse micro-ecosystem. This promotes an even greater possibility than in the case of a single offshore wind farm for alien or invasive species to establish themselves in this part of the Baltic, with negative consequences for the preservation of the naturalness of the local micro-ecosystem. The impact is local, and its magnitude is moderate.

An assessment of the described cumulative impacts is included in Table 24 below.

Table 25. Cumulative impacts of several "artificial reefs" on the BIII offshore wind farm ecosystem (operational phase, NIS 2015)

Cumulative impacts on benthos	The significance of the impact	
	Phytobenthos	Macrozoobenthos
The creation of an "artificial reef"	Small	Small

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015.

9.3. Stage decommissioning

The decommissioning phase will most likely see the removal of most of the farm's facilities from the seabed, in accordance with international regulations for installations and structures in marine areas (United Nations Convention on the Law of the Sea - UNCLOS).

These regulations set conditions for the removal of elements and installation of wind farms in the areas of the continental shelf and the exclusive economic zone. Decommissioning work should be carried out in such a way that it does not impede navigation or adversely affect the marine environment.

The standards also define exceptional situations in which there is no obligation to completely remove infrastructure elements. It is possible to leave such objects when:

- the weight of the foundation in the air exceeds 4,000 tons or is located at a depth of more than 100 meters, provided that it does not cause hindrance to the use of marine areas by other industries,
- decommissioning of elements is technically impossible or too costly,
- there is a threat to the lives of personnel decommissioning the wind farm,
- decommissioning entails an unacceptable risk of pollution of the marine environment.

If some items are left on the seabed, appropriate studies should be conducted to determine whether the farm's remains will not interfere with ship traffic and will not have a negative impact on elements of the living environment.

It should be noted that the removal of farm facilities is one of the options. If the foundations are left in/on the bottom, the impacts on the benthos at this stage will not differ from those at the operational stage.

At the decommissioning stage of OWF BIII, the following impacts on benthos are expected:

1) elimination of the "artificial reef",
2) disruption of sediment structure,
3) an increase in the concentration of suspended solids in water,
4) sedimentation of agitated sediment,
5) the release of pollutants and nutrients from the sediment into the water body.

There may also be unplanned impacts during the decommissioning of the farm, particularly contamination of the water table and bottom sediments:

1) petroleum substances,
2) antifouling agents,
3) accidentally released municipal waste or domestic sewage,
4) accidentally released chemicals and waste from the operation of the farm,

which may indirectly affect the benthos.

Unplanned impacts are assessed in Chapter 11.

9.3.1. Elimination of the "artificial reef"

The dismantling of the artificial hard substrate of the underwater parts of wind turbines is a process that irreversibly destroys the epiphytic assemblages, and partly influences the increase in mortality of the benthos that have colonized the hard substrate around each foundation. This will consequently lead to the loss of habitat and feeding grounds for representatives of ichthyofauna that inhabited the micro-ecosystem of the "artificial reef".

The decommissioning of the "artificial reef" is a direct impact on the BIII offshore wind farm ecosystem, local in scope, long-term, irreversible, repetitive during the decommissioning period, with very high

intensity. It should be noted, however, that in this case, the original assemblage of benthic communities of the BIII offshore wind farm area is no longer subject to assessment, but the biota. **Taking into account that even for the set of parameters of the Project constituting the NIS 2015, the impacts on benthos are not significant and minimization measures are not required, it should be considered that in the case of the Project in the updated parameters, where the number of power plants to be decommissioned and thus the area colonized by benthic organisms will be smaller than in the case of the set of parameters of the Project constituting the NIS 2015, the impacts will also be insignificant.**

An assessment of the significance of this impact **for the furthest-reaching NIS 2015 scenario** , which formed the basis for conducting the environmental assessment in the 2015 Report, is presented in Table 26 below.

Regardless of the variant of the project, all wind turbines will be decommissioned, i.e. the entire artificial reef within the OWF will be destroyed. It is considered that the Project in the revised parameters will not cause impacts on the epiphytic biota greater than the Project in the parameters approved by the Environmental Decision, as well as the 2015 NIS.

Table 26 Assessment of the impact on benthos of decommissioning the "artificial reef" (decommissioning phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Phytobenthos	Small	Average	During the decommissioning stage, the "artificial reef" may be destroyed	Moderate (scale of exposure - local, duration - long-term, intensity - very high)	Small (magnitude of impact - moderate, importance of the resource - low)
Macrozoobenthos	Medium	Average		Moderate (scale of exposure - local, duration - long-term, intensity - very high)	Small (magnitude of impact - moderate, importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015.

Thus, it should be considered that both the nature of the impacts does not change, and their scope and magnitude are not greater than in the case of the variant approved by the Environmental Decision, and thus the change in the parameters of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.3.2. Disruption of the structure of sediments

During the decommissioning of OWF B III, work will be carried out that will cause local disturbance of the bottom sediment structure. These include, in particular, the removal of foundations. Disturbance will also be caused by anchoring vessels and driving the legs of ships and jack-up barges into the seabed to stabilize their position. There will be physical destruction of benthic organisms that repopulated the seabed in the vicinity of the foundations during operations.

Full habitat regeneration at the site of removed foundations can take 3 to 5 years. This depends on the achievement of a stabilized quantitative structure by species forming assemblages characteristic of the sediment type of the BIII offshore wind farm region. The process is shorter for polychaetes and slightly longer for bivalves.

Physical destruction of the benthos resulting from disturbance of the bottom sediment structure at the decommissioning stage is a direct, negative impact of local scope, long-term, i.e. will last longer than 3 growing seasons, reversible, repeatable during the decommissioning period, with very high intensity. No impact is expected on the structure and functioning of the phytobenthos in the buffer zone. **The assessment conducted for the Project in the parameters approved by the Environmental Decision did not predict significant impacts and minimization measures.**

An assessment of the significance of this impact **for the set of parameters of the Project representing the furthest-reaching NIS 2015 scenario** , which formed the basis for conducting the impact assessment in the 2015 Report, is presented in Table 27 below.

Dismantling of foundations is a staged process, so it is considered that regardless of the maximum number of wind power plants (project variants) in a given unit of time a similar number of them will be decommissioned causing similar impacts on a local scale (within the area occupied by several decommissioned wind power plants). Most often, gravity foundations are eliminated by trimming them and hauling them ashore in several pieces. In addition, it is most likely that the internal connection infrastructure cables and the scour protection layer will not be excavated from the seabed, so the disturbance of bottom sediments will be negligible regardless of the project variant. **Therefore, it can be assumed that the Project after the changes will not cause an impact of a magnitude exceeding that assumed for the set of Project parameters constituting the 2015 NIS and for the Project in the parameters approved by the Environmental Decision, and thus the updating of the Project parameters does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained**

Table 27. Impact assessment involving physical destruction of benthos resulting from disturbance of bottom sediment structure (decommissioning phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Phytobenthos	Small	Low or medium	During the decommissioning of the farm, the structure of the bottom sediments will be disturbed, leading to the physical destruction of the benthos	No change (no loss of the resource, no impact on the structure and operation of the resource)	No change (magnitude of impact - no change, importance of the resource - low)
Macrozoobenthos	Medium			Moderate (scale of exposure - local, duration - long-term, intensity - very high)	Small (magnitude of impact - moderate, importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015.

Thus, it should be considered that both the nature of the impacts does not change, and their scope and magnitude are not greater than in the case of the variant approved by the Environmental Decision, and

thus the change in the parameters of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.3.3. An increase in the concentration of suspended solids in water water

As a direct result of the disturbance of the bottom sediment structure during the decommissioning of the farm's elements, there will be a rise and spread of suspended solids in the water-depth, with a range and intensity most likely somewhat less than during the construction phase described in Section 9.1.2 (if no cable decommissioning takes place).

The increase in the concentration of suspended solids in the water, resulting from the disturbance of the bottom sediment structure during the decommissioning stage, will cause a direct negative impact on the benthos of local extent, short-term, reversible, repeatable during the decommissioning period, of medium intensity. Given that the significance of the impact at the decommissioning stage of the BIII OWF on the benthos for the set of parameters of the Project constituting the 2015 NIS is negligible, minimization measures are not required.

An assessment of the significance of this impact for the most far-reaching NIS 2015 scenario, which formed the basis for conducting the impact assessment for the Project approved by the Environmental Decision, is presented in Table 28 below.

Dismantling of foundations is a staged process, so it is considered that regardless of the maximum number of wind power plants (project variants) in a given unit of time a similar number of them will be decommissioned causing similar impacts on a local scale (within the area occupied by several decommissioned wind power plants). Most often, gravity foundations are eliminated by trimming them and hauling them ashore in several pieces. In addition, it is most likely that the internal connection infrastructure cables and the scour protection layer will not be excavated from the seabed, so the increase in suspended solids concentration in the water will be negligible regardless of the project variant. In the case of updating the parameters of the Project, given that the number of power plants to be dismantled will be less than for the set of parameters of the Project constituting the 2015 NIS, as well as less than for the Project in the parameters approved by the Environmental Decision, it is reasonable to assume that it will not cause impacts greater than those caused by the Project approved by the Environmental Decision

Table 28. Assessment of the impact on benthos of increasing suspended solids concentration in water (decommissioning phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Phytobenthos	Small	Low or medium	During the decommissioning of the farm, the structure of the bottom sediments will be disturbed, leading to an increase in the concentration of suspended	Insignificant (scale of exposure-local, duration-short term, intensity-medium)	Negligible (magnitude of impact - insignificant, importance of the resource - low)
Macrozoobenthos	Medium	None, very low or low		Negligible (scale of exposure - local, duration	Negligible (magnitude of impact - insignificant,

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
			solids in the water	- short term, intensity - medium)	importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015.

Thus, it should be considered that both the nature of the impacts does not change, and their scope and magnitude are not greater than in the case of the variant approved by the Environmental Decision, and thus the change in the parameters of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.3.4. Deposition of agitated sediment

As a direct result of the disruption of the bottom sediment structure, suspended solids will be re-deposited on the bottom through the sedimentation process. Sedimentation is likely to be somewhat less extensive and intense than during the construction phase described in Section 9.1.3 (if cables are not decommissioned).

The deposition of agitated sediment on the seafloor, resulting from previous disturbance of the bottom sediment structure and suspended solids spreading, during the decommissioning stage will cause direct negative impacts on the benthos of local extent, short-term, reversible, repeatable during the decommissioning period, with low intensity. Taking into account the fact that even the significance of the impact at the stage of decommissioning of the OWF for the benthos in the variant approved by the Environmental Decision is negligible, and minimization measures are not required, it should be considered, due to the smaller number of power plants to be dismantled in the event of modification of the parameters of the Project, that in this case the scope and magnitude of impacts will not be greater than in the case of the Project in the parameters approved by the Environmental Decision.

An assessment of the significance of this impact for the set of parameters of the Project representing the furthest-reaching NIS 2015 scenario , which was the basis for conducting the assessment in the 2015 Report, is presented in Table 29 below.

Dismantling of foundations is a staged process, so it is considered that regardless of the maximum number of wind power plants (project variants) in a given unit of time a similar number of them will be decommissioned causing similar impacts on a local scale (within the area occupied by several decommissioned wind power plants). Most often, gravity foundations are eliminated by trimming them and hauling them ashore in several pieces. In addition, it is most likely that the internal connection infrastructure cables and the scour protection layer will not be excavated from the seabed, so the deposition of disturbed sediment will be negligible regardless of the project option evaluated in the 2015 Report. It is reasonable to assume that the Project in the parameters of the Project approved by the Environmental Decision will cause an impact on benthos no greater than the set of parameters of the Project constituting the 2015 NIS and no greater than the Project in the parameters approved by the Environmental Decision.

Table 29. Assessment of the impact on benthos of suspended solids deposition on the seabed (decommissioning phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Phytobenthos	Small	Low or medium	During the construction of the farm, the structure of the bottom sediments will be disturbed, leading to an increase in the concentration of suspended solids in the water, followed by their redeposition on the seabed	Negligible (scale of exposure - local, duration - short-term, intensity - low)	Negligible (magnitude of impact - insignificant, importance of the resource - low)
Macrozoobenthos	Medium	None, low or medium		Negligible (scale of exposure - local, duration - short-term, intensity - low)	Negligible (magnitude of impact - insignificant, importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015.

Thus, it should be considered that both the nature of the impacts does not change, and their scope and magnitude are not greater than in the case of the variant approved by the Environmental Decision, and thus the updating of the parameters of the Project does not affect the result of the environmental impact assessment carried out as part of the proceedings during which the Environmental Decision was obtained.

9.3.5. Release of pollutants and nutrients from the sludge into the water body water

The agitation of the bottom sediment associated with the decommissioning of the foundations of farm facilities or the anchoring of ships promotes the passage of contaminants from the sediments to the water depths (Uścinowicz, 2011; Bojakowska, 2001; Frostner, 1980; Bourg and Loch, 1995; Dembska, 2003). This way they can get to it:

- pollutants, including heavy metals and PAHs and PCBs,
- biogenic elements - nitrogen and phosphorus.

This process is described in detail in Chapter 9.1.2 of the assessment of the impact of OWF BIII on the abiotic environment (Volume IV Section 2 of the EIA). The rate of redistribution of pollutants from the sediment to the water body will be slightly lower than during the construction phase of the farm, if the cables connecting the wind turbines are not removed.

The release of pollutants and nutrients from the sediment into the water body, resulting from previous disturbance of the bottom sediment structure during the decommissioning stage, will cause direct negative impacts on the benthos of local extent, short-term, reversible, repeatable during the decommissioning period, with low intensity. Taking into account the fact that during the impact assessment for the Project in the parameters approved by the Environmental Decision, the significance of the impact at the decommissioning stage of the OWF for the benthos for the set of parameters of the Project constituting the NIS 2015 is small or negligible, and minimization measures are not required, as well as the fact that in the case of updating the parameters of the Project the number of power plants

to be dismantled will be reduced, it allows us to conclude that the impacts will be smaller than in the case of the Project in the parameters approved by the Environmental Decision.

An assessment of the significance of this impact for the furthest-reaching NIS 2015 scenario , which formed the basis of the impact assessment conducted in the 2015 Report, is presented in Table 31 below.
The release of pollutants and nutrients from the sludge into the water body will be a process on the verge of measurability regardless of the project variant.

Table 30. Assessment of impact on benthos of released pollutants and nutrients (decommissioning phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Phytobenthos	Small	Low or medium	During the construction of the farm, the bottom sediment structure will be disturbed, leading to the release of pollutants and nutrients from the sediment into the water body, which may affect the benthos	Negligible (scale of exposure - local, duration - short term, intensity - medium)	Negligible (magnitude of impact - insignificant, importance of the resource - low)
Macrozoobenthos	Medium	None, low or medium		Negligible (scale of exposure - local, duration - short term, intensity - medium)	Negligible (magnitude of impact - insignificant, importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015.

Thus, it should be considered that both the nature of the impacts does not change, and their scope and magnitude are not greater than in the case of the variant approved by the Environmental Decision, and thus the updating of the parameters of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.3.6. Impacts cumulative

At the liquidation stage, the accumulation scenario is the most difficult to predict. In the most far-reaching one, all wind farms built are decommissioned at the same time (i.e. depending on the scenario and obtaining additional connection conditions), e.g. as a result of legal changes that make their operation completely unprofitable.

At the decommissioning stage of the BIII OWF, similar cumulative impacts to those from the construction stage (section 9.1.5.) may occur if all underwater wind turbine structures are dismantled at the same time.

The potential accumulation of impacts can be spoken of primarily in the case of the spreading of suspended solids caused by the disturbance of the structure of the bottom sediments, and its subsequent sedimentation. However, the level of this accumulation will be minimal - the spreading of suspended solids resulting from the stirring up of bottom sediments during construction activities only

marginally exceeds the boundaries of the farm, and the thickness of the additional layer of sediment that can settle to the bottom is only 0.2 - 0.6 mm.

A significant portion of the impacts described in Section 9.3 will not be cumulative, due to the scope being limited to the site of the foundation in question or its immediate vicinity. It was considered that the same impacts as during the construction phase, i.e. the disturbance of the sediment structure, the associated increase in the concentration of suspended solids in the water and the deposition of agitated sediment, would accumulate.

An assessment of cumulative impacts during the construction phase is provided in Table 32.

Table 31 Assessment of cumulative impacts on benthos (decommissioning phase, NIS 2015)

Cumulative impacts on benthos	The significance of the impact	
	Phytobenthos	Macrozoobenthos
Disruption of sediment structure	No change	Small
Increase in the concentration of suspended solids in water	Skip	Skip
Deposition of agitated sediment	Skip	Skip

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015.

Changing the conditions for implementation and operation of the Project does not affect the nature, magnitude and significance of impacts in relation to the Project in the parameters approved by the Environmental Decision.

10. Impacts related

The nature of the benthos, i.e. its taxonomic composition, abundance and biomass, is shaped by the physical and chemical factors of the water above the bottom: salinity, oxygen saturation and the type of bottom sediment. The impact of OWF BIII on marine benthos will result from the disturbance and change in the nature of sediments. If the predominant area of the BIII OWF is dominated by sandy sediments, sands on clays and differentiated sediments (Dembska et al., 2015 - Volume III Section 5 of the report), then during the construction and decommissioning of the farm there will be an increased exposure of the benthos to unfavorable suspended solids flow. The benthos will be destroyed in areas where the sediment has been excavated to prepare the bottom for the foundation and leaching protection layer, as well as the cables connecting the wind turbines, in areas of deposition of the excavated spoil, and in areas of foundation placement. It is estimated that the total area of the bottom area degraded as a result of construction in the variant approved by the Environmental Decision will be less than 1% of the area of OWF BIII, and in the case of proposed changes in the parameters of the Project, this figure will be reduced to about 0.4% of the area of OWF BIII. The depletion of the benthic food base for seabirds and fish will not be permanent. The high reproductive potential of benthic species will cause the taxonomic structure to recover after the first growing season, and the return to full recovery of the quantitative state (abundance and biomass) will occur no later than the fifth growing season after degradation, when the longest-lived bivalve species will reach maximum size.

In the area of OWF BIII, two macrozoobenthos communities were found - the *Mytilus trossulus* assemblage, which lives on hard bottom, where gravels and pebbles predominate, and the *Pygospio elegans* assemblage, which occurs on sandy bottom fragments. The construction of an offshore wind farm will cause the greatest changes in the benthic assemblages of the sandy bottom. The introduction of hard substrate (foundations, foundation stabilizing aggregate) into the environment will produce an

"artificial reef" effect. In a short time, the hard surface will be colonized by epiphytic organisms: mussels, barnacles and bryozoans, and in the overexposed zone also by phytobenthic species. Herbivorous crustaceans and snails will appear in large numbers. With the exception of phytobenthic species, the taxonomic composition and quantitative structure of the benthos will be similar to those found in the *Mytilus trossulus* community. Increased biological productivity of benthic species will make the region around the foundations a place for concentration and feeding of many fish species. In addition, inside the BIII farm, hydrological and hydrochemical changes will occur during the operation stage (Chalcinska et al. 2014), which conditions affect the physiology of benthic organisms.

The results and conclusions in this chapter are important for a comprehensive environmental impact assessment. The structure and functioning of the benthos depends on the abiotic conditions (bottom sediments, hydrological and hydrochemical conditions of the headwaters), hence the assessment in the report is related to the results contained in the reports "Studies of physical and chemical conditions of sediments in the area of the OWF "Baltic Central III"(Dembska et al, 2015 - Volume III Section 5 of the report), "Investigations of hydrological and hydrochemical conditions in the area of the OWF "Baltic Central III"(Chalacińska et al., 2015 - Volume III Section 2 of the report) and the report on modeling, among others, of hydrographic conditions and suspended solids spreading at the stage of construction of the offshore farm (Volume II Section 11 of the report. In addition, the conclusions of this report are the basis for the assessment of associated impacts in the reports on the assessment of the impact of OWF BIII on ichthyofauna (Volume IV Section 4 of the report), fisheries (Volume IV Section 10 of the report) and birds (Volume IV Section 5 of the report).

11. Impacts unplanned

Unplanned impacts are the result of sudden events or failures that are not related to activities included in the project schedule (e.g., leakage of toxic substances into the water due to a collision between two vessels).

A full description of potential unplanned events can be found in Section 12 of Volume II of the report. The assessment of the significance of unplanned impacts on benthos took into account the probability of the event that will be the source of the impact and its potential consequences.

Based on data from other OWF projects and similar projects, as well as the 2015 Report, the following potential unplanned impacts were selected:

1) leakage of petroleum substances as a result of a collision, accident or construction disaster (during normal operation or in an emergency);
2) accidental release of municipal waste or domestic sewage;
3) accidental release of construction materials or chemicals;
4) contamination of the water tone and bottom sediments with antifouling agents;
5) disruption of sediment structure, agitation and sedimentation on the bottom associated with unexploded conventional weapons (UXO) explosions.

It should be noted that as a result of unplanned events , the abiotic environment, primarily marine waters and, to a lesser extent, bottom sediments, may be directly contaminated. On the other hand, indirectly, these events can also affect living organisms that inhabit or otherwise use the seabed, the water table and the sea surface.

A full description of potential unplanned events can be found in Section 12 of Volume II of the report. In contrast, **indirect impacts of unplanned events on benthos** are **assessed** below, based on this description.

11.1. Spill of petroleum substances (during normal operation of the vessels)

During normal ship operation, spills of various types of petroleum substances (lubricating and diesel oils, gasoline) can occur.

Under favorable conditions, leaks can disappear spontaneously due to evaporation and dissipation in water. The size of these spills will be practically limited to the OWF area.

They may contribute slightly to the deterioration of water quality. Heavier oil fractions can be sorbed on the surface of organic and mineral suspensions, which will cause their specific gravity to increase and gradually sink to the bottom. There they can be bound by bottom sediments. However, due to the nature of the sediments in the BIII offshore wind farm area (small amount of organic matter and low content of fine fractions), they will not cause any noticeable deterioration in their quality. It should be assumed that these spills will be small (stage I), up to 20^{m3}. Visible traces of such contamination under favorable conditions can disappear spontaneously due to evaporation and dispersion in the water. The size of these spills will be practically limited to the OWF area. The contamination of sediments with petroleum substances is independent of the type of foundation used. It will be more noticeable in areas with fine-grained sediments, which have a greater capacity to absorb petroleum substances.

As a primary minimization measure, it is recommended that vessels be supplied with means to deal with minor oil spills. Mitigation activities are described in more detail in Section 12 of Volume II of the EIA.

The impact on the benthos of a small amount of petroleum substances released into the sea during normal ship operations is assessed as **an indirect, negative, local in scope, temporary or short-term, reversible, repetitive, low-intensity** impact.

An assessment of the significance of this impact on benthos regardless of the stage of implementation of OWF BIII and the project variant is presented in the table below. Changing the parameters of **the Project to those specified in the Environmental Decision will not affect either the risk or the magnitude of the impact caused by an oil spill into the sea.** The significance of the unplanned impact - oil spills on the benthos of OWF BIII, will be negligible or small.

Table 32. Assessment of the impact on the benthos of oil substances released into the sea during normal ship explorations regardless of the stage of implementation of OWF BIII and the project variant

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Phytobenthos	Small	Average	In emergency situations, contamination of water depths and bottom sediments with oil-based substances may occur	Insignificant (scale of exposure - local, duration - temporary or short-term, intensity - low)	Negligible (magnitude of impact - insignificant, importance of the resource - low)
Macrozoobenthos	Medium	Average		Insignificant (scale of exposure - local, duration -	Negligible (magnitude of impact - insignificant,

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
				temporary or short-term, intensity - low)	importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015.

11.2. Spill of petroleum substances (in an emergency situation emergency)

During the construction, operation or decommissioning of the farm, leakage of petroleum substances may occur, resulting in pollution of the water table and bottom sediments. A spill can occur as a result of a shipwreck or collision, a construction disaster at one of the farm's facilities, or during maintenance work. In the event of a collision or collision between ships, a Grade III spill, i.e. over 50^{m3}, can be expected.

It has been calculated that the probability of serious accidents is very low, on the order of $^{10-5}$ - $^{10-4}$. For the Southeast Baltic, which may include the BIII offshore wind farm area, the risk of collision was estimated at 1 case per 1060 years. The significance of this impact can be considered negligible, as the unplanned impacts described are extremely rare and practically impossible. In this case, there are organizational structures, plans of conduct in carrying out actions to combat hazards and pollution, and effective methods of cleaning up pollution.

However, if an oil spill were to occur in the area of OWF BIII during its construction, 24 hours after the accident at a probable wind direction distribution for the Southern Baltic of 3°B, its extent would cover the eastern slope of Slupsk Shoal (Pawelec et al. 2014), threatening not only the benthic organisms of the farm area, but the Slupsk Shoal Natura 2000 area, which protects, among other things, the habitat of marine clam beds and many species of macroalgae. In the best-case scenario (calm sea), oil splashes will not threaten the benthos, but only groups of organisms living in the water's depths. During a storm, the dispersion of the oil spill will contaminate the food chain in the area of the failure (Malaczynski and Czarnecki 2010). If petroleum products reach the bottom sediments where they accumulate, they will simultaneously be a major toxic and carcinogenic threat to benthic organisms, reducing their physiological condition. In addition, the effects of spills can be catastrophic for the benthos for several months after an accident due to a decrease in the amount of oxygen reaching the bottom zone (Rogowska 2011).

The impact on the benthos of more petroleum substances released into the sea during an accident or collision is assessed as **indirect, negative, regional in scope, short-term, reversible, repetitive, high-intensity** impact.

An assessment of the significance of this impact **for the most far-reaching scenario, the 2015 NIS,** is presented in the table below.

Table 33 Assessment of the impact on benthos of more petroleum substances released into the sea during an accident or collision (unplanned impacts, any stage, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Phytobenthos	Small	Average	In emergency situations, contamination of water depths and bottom sediments with oil-based substances may occur	Small (scale of exposure - regional, duration - short-term, intensity - high)	Negligible (magnitude of impact - low, importance of the resource - low)
Macrozoobenthos	Medium	Average		Small (scale of exposure - regional, duration - short-term, intensity - high)	Small (magnitude of impact - negligible, importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015.

Changing the parameters of **the Project to those specified in the Environmental Decision will not affect either the risk or the magnitude of the impact caused by an oil spill into the sea.** The significance of the unplanned impact - oil spills on the benthos of OWF BIII, will be negligible or small.

11.3. Accidental release of municipal waste or wastewater domestic

During the construction of the wind farm, waste, mainly municipal and other waste not directly related to the construction process, as well as domestic sewage, will be generated on vessels as well as at the construction facilities located on land (at the port serving the project). Their expected types of quantities, as well as how they will be handled, are presented in Section 10 of Volume II of the EIA. Waste and wastewater can be accidentally released into the sea when picked up from ships by another vessel and in the event of an accident, causing a local increase in nutrient concentrations and deterioration of water and sediment quality, and indirectly negatively affecting the benthos. However, the pollutants should quickly disperse, so they will not contribute to permanent deterioration of the environment in the project area.

As a minimizing measure, it is recommended to create procedures related to waste and wastewater handling.

The impact on the benthos of a small amount of municipal waste or domestic sewage accidentally released into the sea is assessed as an indirect, negative, local in scope, short-term, reversible, repetitive, low-intensity impact.

An assessment of the significance of this impact for the set of parameters of the Project representing the most far-reaching scenario, the 2015 NIS, is presented in the table below.

Changing the parameters of the Project will not result in either an increase in the amount of waste and domestic sewage, or in the amount of maintenance operations, and it is expected that due to the smaller number of power plants in relation to the parameters of the Project approved by the

Environmental Decision, the amount of impact generated by the Project under the modified parameters will be less.

The significance of the unplanned impact - contamination with construction and operational materials of the OWF BIII benthos, will be negligible.

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Phytobenthos	Small	Average	During the construction, operation or decommissioning of the farm, a small amount of municipal waste or domestic sewage may be accidentally released into the sea	Negligible (scale of exposure - local, duration - short-term, intensity - low)	Negligible (magnitude of impact - insignificant, importance of the resource - low)
Macrozoobenthos	Medium	Average		Negligible (scale of exposure - local, duration - short-term, intensity - low)	Negligible (magnitude of impact - insignificant, importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015.

11.4. Accidental release of chemicals and waste from construction, operation or decommissioning of the farm

During the construction of the wind farm, waste directly related to the construction process will be generated on vessels, at construction facilities located onshore (at the port serving the project) and at the project site. These can include damaged parts of the farm's assembled components, cement, grout, mortar, binders used to join the foundation and power plant components, and other chemicals used during construction work. They can be accidentally released into the sea.

The bulk cement is packed in bags of about 1^{m3}. It was assumed that about $5^{m3\ of}$ product could sink during handling. Grouts, mortars and other binders often contain hazardous substances. E.g., epoxy (two-component) grouts contain in various proportions: epoxy resin, alkyl glycidyl ethers, polyamines. Once they enter the water depths, due to their high density of about 1.3 $^{g\text{-}cm\text{-}1}$, they sink and are deposited on the bottom. These substances are considered a serious threat because they cannot be easily removed from the bottom and are toxic to marine organisms.

During the operation of the farm, maintenance of its facilities will be carried out. Accidental discharge of waste or operating fluids into the sea cannot be ruled out, which may end up deposited on the bottom.

During decommissioning of the farm, it seems inevitable that bottom sediments will be contaminated with waste from the process. The magnitude of this impact will depend on the method adopted for carrying out this work (cf. description of the decommissioning stage), and the greatest contamination may occur if gravity foundations have to be crushed.

The anticipated types and quantities of waste are presented in Section 10 of Volume II of the EIA.

For this type of investment like the OWF, a detailed plan is being developed to counteract the risks and pollution arising during the construction, operation and decommissioning of the OWF, which includes a description of minimization measures and how to deal with such events. It is recommended that such procedures be created as a minimization measure.

The impact on the benthos of construction and operation materials that may accidentally enter the sea during the construction, operation or decommissioning of the farm is assessed as a direct or indirect, negative, local in scope, short-term, reversible, repetitive, medium intensity impact.

The assessment of the significance of this impact on benthos regardless of the stage of implementation of the BIII OWF carried out in the 2015 Report is presented in Table 34 below. **Changing the parameters of the Project will not result in either an increase in waste or maintenance operations, and it is expected that due to the smaller number of power plants relative to the parameters of the Project approved by the Environmental Decision, the magnitude of impact generated by the Project under the modified parameters will be less.** The significance of the unplanned impact - contamination with construction and operational materials of the OWF BIII benthos, will be negligible or small.

Table 34. Assessment of the impact on benthos through contamination of the seabed by construction and operational materials regardless of the stage of implementation of OWF BIII and the variant of the project

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Phytobenthos	Small	Average	During the construction, operation or decommissioning of the farm, there may be accidental release of waste associated with the process into the sea, and at any stage of the project there may be accidental release of various types of chemicals	Negligible (scale of exposure - local, duration - short term, intensity - medium)	Negligible (magnitude of impact - insignificant, importance of the resource - low)
Macrozoobenthos	Medium	Average		Negligible (scale of exposure - local, duration - short term, intensity - medium)	Negligible (magnitude of impact - insignificant, importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015.

11.5. Contamination of water depths and bottom sediments with agents antifouling

To protect the hulls of ships from overgrowth, biocides are used, which may include, for example, copper compounds, mercury compounds, organotin compounds (such as tributyltin - TBT). These substances can pass into the water's depths and eventually be retained in the sediment. It should be assumed that the emission of these compounds will be limited by dilution in the water depths. Of the substances listed, organotin compounds are the most harmful (toxic) to aquatic organisms. TBT (the most harmful substance) is currently banned in antifouling paints, but the presence of these compounds in older units cannot be ruled out.

As a minimizing measure, it is recommended that vessels whose hulls have not been coated with TBT-containing antifouling paint be used at any stage of the project. This will eliminate this most harmful impact on aquatic organisms.

The impact on the benthos of antifouling agents is assessed as **indirect, negative, local in scope, temporary or short-term, reversible or irreversible, repetitive, low intensity**.

The assessment of the significance of this impact on the benthos regardless of the stage of implementation of OWF BIII carried out in the 2015 Report is shown in Table 35 below

Changing the parameters of **the Project to those specified in the Environmental Decision will not affect both the risk and magnitude of the impact through contamination of the water depth and bottom sediments with antifouling agents. Due to the smaller number of power plants in relation to the parameters of the Project approved by the Environmental Decision and, consequently, the smaller number of maintenance operations, the magnitude of the impact generated by the Project under the modified parameters will be lower**

Table 35 Assessment of impacts on benthos of antifouling agents released into the sea (unplanned impacts, any stage, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Phytobenthos	Small	Average	During the normal operation of ships, the release of antifouling substances from their hulls may occur	Negligible (scale of exposure - local, duration - temporary or short-term, intensity - low)	Negligible (magnitude of impact - insignificant, importance of the resource - low)
Macrozoobenthos	Medium	Average		Negligible (scale of exposure - local, duration - temporary or short-term, intensity - low)	Negligible (magnitude of impact - insignificant, importance of the resource - medium)

Source: Offshore wind farm Central Baltic III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015.

11.6. Disruption of sediment structure, secondary sedimentation on the bottom, and increased suspended solids associated with UXO explosions

If UXO detonation is carried out, it is possible to disrupt the structure of bottom sediments, agitate and redeposit them, and increase suspended solids in the water.

In the case analyzed, impacts are expected to be analogous to those of physical interference with the bottom during the construction phase (see Section 9.1 of this Section).

As a direct result of the disturbance of the bottom sediment structure, suspended solids will rise and dissipate (resuspension) in the water depths, potentially releasing pollutants and nutrients into the water, re-depositing on the bottom. Some heavy metals, pollutants and nutrients may be released from the bottom sediments as a result of the agitation, analogous to the construction phase. In this case, there may be a deterioration of water quality due to an increase in the concentration of harmful and biogenic substances (due to the passage from the sediment to the water body as a result of sediment uplift processes). These sediments will also promote the formation of more suspended solids, which will persist in the water depths for a long time. Intense resuspension can cause the release of nutrients

immobilized in the sediment and contribute to eutrophication. In the case of sandy sediments with low organic matter content (e.g., coarse-grained sandy sediments), the processes described will be less intense. These sludges are generally characterized by small amounts of fine fractions and low concentrations of metals and persistent organic pollutants.

It is also assumed that there may be temporary turbidity in the water due to an increase in suspended solids in the water. Aggradation of bottom sediments can also affect potential mineral accumulations.

The scale of anticipated impacts will vary depending on the size of the detonated cargo, but nevertheless they are not expected to extend beyond the local range. All potential impacts on the benthos associated with the decommissioning of UXO, with the exception of physical destruction of the benthos due to disturbance of the sediment structure, were assessed as insignificant. Since phytobenthos was only recorded in the buffer zone of the farm during the environmental studies, it is not expected that the detonation of UXO could cause its physical destruction. In the case of macrozoobenthos, the significance of the impact involving its physical destruction, due to the long-term nature of the effects (recovery of the population to its original state occurs after about 5 years) and its high intensity, was considered low. An assessment of the significance of the impacts in question is presented in the tables below.

Table 36 Impact assessment of physical destruction of benthos resulting from disruption of bottom sediment structure due to UXO explosion (any stage)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Phytobenthos	Small	Low or medium	Due to the detonation of UXO, the structure of the bottom sediments will be disturbed, leading to the physical destruction of the benthos	No change (no loss of the resource, no impact on the structure and operation of the resource)	No change (magnitude of impact - no change, importance of the resource - low)
Macrozoobenthos	Medium			Moderate (scale of exposure - local, duration - long-term, intensity - very high)	Small (magnitude of impact - moderate, importance of the resource - medium)

Table 37. Assessment of the impact on benthos of an increase in suspended solids concentration in water due to UXO explosion (any stage)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Phytobenthos	Small	Low or medium	Due to the detonation of UXO, the structure of the bottom sediments will be	Negligible (scale of exposure - local, duration - short term, intensity - medium)	Negligible (magnitude of impact - insignificant, importance of

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
			disturbed, leading to an increase in the concentration of suspended solids in the water		the resource - low)
Macrozoobenthos	Medium	None, very low or low		Negligible (scale of exposure - local, duration - short term, intensity - medium)	Negligible (magnitude of impact - insignificant, importance of the resource - medium)

Table 38. Assessment of the impact on benthos of the deposition of suspended solids on the seabed in the growth of the result of UXO explosion (any stage)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Phytobenthos	Small	Low or medium	Due to the detonation of UXO, the structure of bottom sediments will be disturbed, leading to an increase in the concentration of suspended solids in the water and their subsequent redeposition on the seabed	Negligible (scale of exposure - local, duration - short-term, intensity - low)	Negligible (magnitude of impact - insignificant, importance of the resource - low)
Macrozoobenthos	Medium	None, low or medium		Negligible (scale of exposure - local, duration - short-term, intensity - low)	Negligible (magnitude of impact - insignificant, importance of the resource - medium)

The 2015 report did not include an assessment of unplanned impacts associated with UXO detonation. The assessment conducted in this report indicates that the magnitude and significance of the impact is insignificant. At the same time, it should be emphasized that the Project update does not affect the Project's impacts in relation to the Project in the parameters approved by the Environmental Decision. The possibility of such an impact is related to the area of the seabed covered by the works during the course of the project, and this will not change even after the implementation of the proposed changes to the conditions of the Environmental Decision.

11.7. Impacts cumulative

In the event of simultaneous construction, operation or decommissioning of several projects, vessel traffic in adjacent areas increases, with an increased risk of collisions and emergency oil spills and simultaneous accidental discharge of construction and operational materials into the sea.

In the case of simultaneous implementation or operation of several projects, vessel traffic in neighboring areas also increases, with an increased risk of such an event. To the north of the farm is a heavily used shipping route, in the area of which there is an increased risk of oil spills.

The cumulative impact of all unplanned impacts on the benthos will be the same as for the individual impacts described in sections 11.1. - 11.6.

12. Assessment of the impact of the project integrity, coherence and object of protection of Natura 2000 areas

This chapter analyzes the potential for impacts of the BIII OWF, individually and in cumulation with other projects, on the integrity, coherence and objects of protection of Natura 2000 areas in the context of benthos. The assessment was performed in accordance with the methodology described in Section 5 of Volume I, paragraph 4.3.13.

12.1. Initial assessment - screening

Pre-assessment is the process by which the project's likely impacts on Natura 2000 sites are identified (either singly or in conjunction with other projects or plans). An analysis is made of whether the projected impacts could have a significant impact undermining the conservation objectives of these areas (EU Guidance on wind energy, 2011).

12.1.1. Zone of potential impacts of the OWF BIII

After analyzing the impacts of OWF BIII, as described in this document, it was found that the project's impacts on benthos will be overwhelmingly limited to the area of the farm.

However, the following secondary impacts may extend beyond the farm area:

- resulting from the rise and spread of suspended solids in the water depths and their redeposition to the bottom, thereby covering benthic habitats and protected habitats in the Slupsk Bank PLC990001 Natura 2000 area. This indirect impact will be a direct result of the disturbance of the bottom sediment structure during construction activities (and to a lesser extent during operation and decommissioning of the farm). Its range, in the farthest-reaching scenario, up to a dozen kilometers, is shown in the figures below.
- resulting from the effect of changes in benthic habitats that are a source of food for seabirds that are protected in Natura 2000 areas. Its range will be up to several kilometers.

The variant that is the subject of this Report will build about. 70% fewer foundations than envisaged for the furthest-reaching scenario - NIS 2015 - forming the basis of the assessment in the 2015 Report, and twice as few as specified in the Environmental Decision, and the use of the most invasive gravity foundations under the power plants has been excluded, limiting the permissible foundation types to monopile and jacket type only, and only in the case of additional infrastructure has the possibility of using gravity foundations been retained, but their number has been limited to one (out of 6 permitted under the terms of the Environmental Decision). It is associated with a significantly lower extent of all impacts on benthos during the construction, operation and decommissioning phases. Thus, it is considered that if the proposed modifications are implemented, the disturbance that is a source of suspended solids uplift and dissipation in the water body, as well as secondary sedimentation, will also be significantly reduced, thus further reducing the potential for impacts on Natura 2000 sites compared to the Project in the parameters constituting the 2015 NIS, as well as the variant approved in the Environmental Decision.

12.1.2. Natura 2000 areas in the zone of influence of the BIII OWF

The zone of potential impacts of OWF BIII on benthos may include 2 areas.

- Slupsk Shoal PLC990001 - about 5.5 km westward from OWF BIII.
- Coastal waters of the Baltic PLB990002 - about 8 km in a southerly direction from OWF BIII;

These areas are described below.

Slupsk Shoal" Natura 2000 area PLC990001

Slupsk Shoal Natura 2000 site PLC990001, which is also an IBA PLM1 sanctuary, is located to the west, at a distance of about 5.5 km from OWF BIII. It is a bird sanctuary of European rank E 79.

Slupsk Shoal is a body of water in the southern Baltic Sea, encompassing an area with a highly varied bottom with numerous hills and depressions with depths ranging from about 8.0 to about 35.0 meters. The shallowest parts of the bottom include elevations within the so-called "boulder pit" in the northern and western parts of the area (minimum depth of about 8.0 m) and parts of the sandy bottom of the central part of the area (minimum depth of about 12.0 m). The deepest parts of the bottom (up to 35 m) are located in the southeastern part of the area. The dominant plants are macroalgae, with many species already disappearing in the Gulf of Gdansk. There are no bird species from Annex I of Council Directive 79/409/EEC. During the winter there is at least 1% of the long-tailed duck (C3) migratory path population of the following species: long-tailed duck, guillemot, uha. Wetland birds occur in concentrations of more than 20000 individuals (C4). Isolated are the sites - habitat 1170 (marine bivalve shoals) in Polish marine waters. The shallows are inhabited by numerous invertebrates, providing a rich food base for the flocks of wetland birds that stop in autumn and winter here. It is the site of the crayfish Delesseria sanguinea, which is considered lost in the Baltic Proper.

Natura 2000 area "Baltic coastal waters" PLB990002

The Przybrzeżne wody Bałtyckie PLB990002 Natura 2000 site, which is also an IBA PLM2 site and a bird sanctuary of European rank E 80, is located to the south, at a distance of about 8 km from OWF BIII. It covers the coastal waters of the Baltic Sea with a depth of 0 to 20 meters. Its boundaries stretch for 200 kilometers, starting from the base of the Hel Peninsula and ending at the Pomeranian Bay. The seabed is uneven, with denivelations reaching 3 meters. The area is wintered in significant numbers by 2 species of birds from Annex I of Council Directive 79/409/EEC: black-throated diver and red-throated diver (C7). During the winter there is more than 1% of the long-tailed duck's migratory path (C3) population, at least 1% of the guillemot and uhla. The benthic fauna is dominated by small crustaceans. Large marine mammals - gray seals *Halichoerus grypus* and ringed seals *Phoca hispida* and porpoises Phocaena *phocaena*- are rarely observed.

12.1.3. The object of protection of Natura 2000 areas in the zone impacts

The object of protection of Natura 2000 areas in the zone of impacts of OWF BIII on benthos is presented in the following tables.

Table 39 Slupsk Shoal PLC990001 - types of natural habitats found in the area and assessment of the importance of the area for these habitats:

The conservation objective of none of the above areas is benthic species. However, benthic species are taken into account in the assessment of the status of the two habitats protected in the Natura 2000 area Slupsk Shoal PLC990001 as indicators of their specific structure and function. They are also the basis for the preservation of the proper conservation status of the benthophagus wintering in the area. Habitat 1110 assesses the presence of *habitat-typical* macrozoobenthos species (i.e. *Bathyporeia pilosa, Mya arenaria, Pygospio elegans* and *Cerastoderma glaucum*), while Habitat 1170 assesses the presence of *habitat-typical* macroalgal taxa (i.e. *Furcellaria lumbricalis, Ceramium spp*. And *Vertebrata fucoides*) and taxa of phytophilic epiphytic fauna (i.e., *Amphibalanus improvisus, Einhornia crustulenta, Mytilus trossulus,* and gudgeons of the genus *Gammarus sp.*) (Michalek et al. 2019[2]) (Baranska et al. 2019[3]).

The following is a brief description of the natural habitats protected in the area.

Natural habitat 1110 consists of sandbanks in the sublittoral, permanently submerged under water, the depth of which rarely exceeds 20 meters. Within the habitat, bottom vegetation is mostly absent, except for algae overgrowing individual stones lying on the sand. However, groupings of benthic invertebrates with high species diversity are characteristic of habitat 1110. The criteria in question are met by the predominantly sandy sedimentary part of the Slupsk Shoal. In terms of ecological and biological importance, sandbanks in the southern Baltic Sea are, above all, an important wintering site for many species of seabirds (Warzocha 2004a).

Natural habitat 1170 consists of submerged underwater and elevated above the surrounding seabed rocky substrate in the sublittoral zone. Reefs promote zonal distribution of plants and animals and high biodiversity. The habitat area includes the northwestern part of Slupsk Shoal, with a bottom composed of boulders and stones, with rich plant communities and shoals of mussels. The water depth is about 8-17 m. The hard bottom and the relatively high transparency of the water create favorable conditions for the development of benthic macroalgal communities. This is the only place in the Polish Maritime Areas that is so far from the shore where mass occurrences of benthic vegetation communities can be found (Warzocha 2004b).

An assessment of the conservation status of habitats 1110 and 1170 at sites located in the Slupsk Shoal Natura 2000 area PLC990001 was carried out within the framework of the project entitled: *"Pilot implementation of monitoring of marine species and habitats in 2015-2018"* (implemented as part of the State Environmental Monitoring).

As a result of the 2016-2018 monitoring studies:

[2] As the methodology does not specify the date of its development/publication, the date of access is given.
[3] As the methodology does not specify the date of its development/publication, the date of access is given.

all three parameters of habitat 1110: Area, Specific structure and functions (including both indicators, viz: *Macrozoobenthos Typical Species and Bottom Sediment Status*) and Conservation Prospects were rated at FV (fair condition);

all three parameters of habitat 1170: Area, Specific structure and functions (including both indicators, i.e.. *Typical Taxa of Macroalgae and Typical Taxa of Sporophilous and Phytophilous Fauna*) and Conservation Prospects were assessed at FV (proper condition).

Thus, the conservation status of both habitat types on Slupsk Shoal was assessed as adequate (Baranska et al. 2018).

12.1.4. Impacts of OWF BIII on the object of protection, integrity, coherence of Natura 2000 areas

As can be seen from the analyses performed, the results of which are presented in section 9.1.3. above, the sediment stirred up during the construction works of the farm, falling down, depending on the variant of the project, will cover the bottom to an average thickness of 0.2 - to 0.4 mm, which is shown on the above maps (Figures 7 and 8) in dark blue, also within the boundaries of the Slupsk Shoal Natura 2000 area. The amount of suspended solids carried is so small that it can be compared with the rate of sedimentation in Baltic waters, which ranges from 0.005 to about 0.2 mm/year per year (Gradzinski et al., 1986). The amounts of suspended solids transferred to Natura 2000 areas are, from a practical point of view, unmeasurable. Impacts on the benthic habitats of both areas from OWF BIII should be considered negligible.

Some heavy metals, pollutants and nutrients will be released from the bottom sediments as a result of the agitation, as discussed in detail in Section 9.1.4. There will also be a temporary turbidity of the water. However, these impacts will not result in significant associated impacts on benthic habitats, as well as birds that are the subject of protection of the above Natura 2000 areas, as further described and evidenced in Section 5 of Volume IV.

The impact of changes in benthic habitats in the BIII OWF area (destruction of habitats during the construction phase, followed by their recolonization and the so-called "artificial reef" effect) was considered insignificant, due to the crowding effect that the BIII OWF will have on seabirds, including bentophagous birds that could benefit from the feeding base in the farm area. This issue is described and evaluated more extensively in Section 9.2.5. Section 5 of Volume IV Seabird Impact Assessment.

12.1.5. Zone of potential impacts cumulative

The assessment in the 2015 Report, cited in Section 9.1.5, pointed to the results of the cumulative impacts assessment, stating that the cumulative impacts on benthos increased by about 16.5% above the level analyzed in the 2015 Report for the set of parameters of the Project representing the most far-reaching scenario of the 2015 NIS, which was assessed as having a negligible impact on the increase in the zone of potential impacts.

The potential cumulation of impacts can be spoken of primarily in the case of the spreading of suspended solids caused by the disturbance of the structure of bottom sediments, since, as can be seen from Figures 5 -6 in Section 9.1.2 and Figures 7 - 8 in Section 9.1.3, they can sink to the bottom even at a distance of several kilometers from the site of construction activities. Also associated with the dissolution of suspended solids is the release of a certain pool of pollutants and nutrients from the sediment into the water body and the turbidity of the water. However, an analysis of the aforementioned drawings also allows us to conclude that the level of this accumulation will be minimal - in the course of the works, the raised suspended solids will only marginally exceed the boundaries of the farm and the thickness of the layer of suspended solids that will sink to the bottom is only 0.2 - 0.6 mm in most of the area, which does not cause a significant impact on benthic habitats. The 16.5% increase in the listed impacts is insignificant.

The range of impacts of the BIII OWF will be further increased by the cumulative impacts caused during the laying of the export cable, which will run through both of the above Natura 2000 areas.

The BIII OWF in its planned modified parameters assumes the construction of 60 wind turbines, which represents 30% of the wind turbines evaluated in the 2015 NIS, which is the basis for the BIII OWF benthic impact assessment. In addition, the modified parameters of the Project assume the abandonment of the possibility of gravity and tripod foundations, i.e. the solutions with the greatest significance from the point of view of the impacts of potential impacts on benthos.

In the case of implementation of the Project in the proposed revised parameters, there will be no impacts beyond those assessed in the proceedings during which the Environmental Decision was issued, even after taking into account the Baltic Power SHPP project, for which an environmental decision has since been issued.

12.1.6. Natura 2000 areas in the cumulative zone impacts

There are no other areas in the zone of cumulative impacts of the BIII OWF, apart from the areas of Slupsk Shoal and Baltic Coastal Waters described above.

12.1.7. Object of protection of Natura 2000 areas in the zone of cumulation impacts

In the zone of cumulative impacts of the BIII OWF, there are no Natura 2000 sites other than those described above.

12.1.8. Cumulative impacts of OWF BIII on the object of protection, integrity, coherence of Natura 2000 areas

At the stage of construction and decommissioning of the BIII OWF, the impacts of the planned farm on the natural habitats under protection in the Slupsk Shoal Natura 2000 area, as well as the benthic resources constituting the food base in the Natura 2000 areas, associated with the agitation of bottom sediments and their subsequent sedimentation, may potentially cumulate with analogous impacts caused by the implementation of works in the Baltica 3 Area under the Baltica OWF project (Baltica 3) and the BIII MIP. Since the impacts associated with the planned BIII OWF on the natural habitats under protection in the Slupsk Shoal Natura 2000 area, as well as on the benthic resources found in Natura 2000 areas, will be negligible, they will not result in amplification of the impacts of other projects due to cumulative effects.

In the report on the environmental impact of the Baltic offshore wind farm (IMG Consortium and MEWO et al. 2017), the following assumptions were made in determining the extent of the impact of the increase in suspended solids concentration in the water tone and the resulting sedimentation:

- the maximum range of suspended solids with a concentration of 4 mg/L is 5 km from the site;
- the maximum extent of the sedimentation area of suspended solids with a thickness of 1.5 mm is 2 km.

Taking into account the distance separating the OWF Baltica 3 from the Slupsk Shoal Natura 2000 area, which is more than 11 km from its development area, it can be concluded that the Natura 2000 area in question is outside the above-mentioned range of influence of the suspension. Therefore, the impacts of OWF BIII and OWF Baltica 3 on the natural habitats under protection in the Slupsk Shoal Natura 2000 area, as well as the benthic resources in the said area, resulting from the agitation of bottom sediments will not be cumulative.

It is expected that due to the construction of the BIII OWF in the eastern part of the Slupsk Shoal Natura 2000 area, there may be a slight increase in the concentration of suspended solids at the bottom below 2 mg/L (see Figure 4). Regarding the anticipated extent of suspended solids impact from the construction of MIP BIII, the authors of the environmental impact report for the project in question (BDEI 2016), cite the results of studies conducted during the laying of the SwePol Link cable, which indicate that the turbidity of the water was short-lived and occurred locally only in a small area, and that the greatest turbidity was limited to the area of close proximity under and around the dredge, with a gradual decrease to completely clear water a few tens of meters away. Therefore, the possible cumulative impact of increased suspended solids concentrations due to the implementation of OWF BIII and MIP BIII within the Slupsk Shoal Natura 2000 area will be insignificant.

As indicated in the report on the environmental impact of the BIII MIP (BDEI 2016), as a result of its implementation, a fragment of habitat will be lost in the Slupsk Shoal area, while the increase in suspended solids and its sedimentation process resulting from the foundation of the MIP cables may cover the southern part (the place of bifurcation of the MIP corridor into the section connecting with OWF BII and OWF BIII) and the northern part of the Slupsk Shoal, and in these places the additional thickness of sediments after the execution of works along the entire route will not exceed 15 mm. Thus, it can be concluded that even if suspended sedimentation were to occur in the same part of the Slupsk Shoal area due to both MIP BIII and OWF BIII, the expected maximum thickness of the additional

sediment layer deposited due to the construction of the planned farm (up to 0.04 mm) would in no way affect the scale of the disturbance in question.

In the case of the Natura 2000 area Przybrzeżne wody Bałtyku PLB990002, there are no objects of protection in the form of natural habitats, while the even greater distance of OWF BIII from the borders of the Natura 2000 area means that there is no risk of impacts that could lead to the effect of changes in benthic habitats that are a source of food for seabirds that are the subject of protection in the Natura 2000 area.

In conclusion, the BIII OWF will not cause significant impacts on habitats under protection in the Slupsk Shoal Natura 2000 area, as well as benthic resources occurring about Natura 2000 areas, and related to the agitation of bottom sediments in cumulation with the above-mentioned projects.

12.1.9. The result of the assessment preliminary

Taking into account the type and scale of impacts of OWF BIII, it is not expected that the planned farm could, alone or in accumulation with other projects, have a significantly negative impact on the natural habitats that are the objects of protection in Natura 2000 areas, as well as benthic resources in it, conditioning the integrity of the areas in question. Thus, there is no basis for a proper assessment on Natura 2000 sites.

13. Impacts transboundary

The BIII OWF is not expected to cause transboundary impacts, i.e. to affect benthos within the borders of other countries (including their exclusive economic zones), either alone or in cumulation.

According to the assessment, the impact of OWF BIII has an overall low impact on the status and habitat of the benthos. The impact is only local, limited to the area of the farm. Based on EEZ boundary data in the Baltic Sea (http://maps.helcom.fi/website/mapservice/index.html) the minimum distances of OWF BIII from EEZs of other countries were calculated. The minimum distance of the BIII OWF to the EEZ border of Sweden will be about 52 km, to Denmark - 57 km, to Russia - 104 km and to Germany - 170 km. In addition, with limited cumulative impacts, the planned project will not generate transboundary impacts.

14. Proposal monitoring

The Project update does not affect the conditions for monitoring specified in the Environmental Decision. The conditions and rules for conducting benthic monitoring are specified in the Environmental Decision in section 2.2.a at the stage of construction of OWF BIII and 2.2.c at the stage of operation of OWF BIII and 2.2.b at the stage of decommissioning of OWF BIII. Nor is it the subject of this Report to change these conditions.

15. Summary and conclusions

According to the results of the assessment of the impact of OWF BIII on benthos, modification of the parameters of the Project in relation to those approved by the Decision on environmental conditions will not change the nature, scope or magnitude of the impacts caused. Consequently, based on the results of the assessment presented for the Project in the parameters approved by the Environmental Decision, it should be concluded that OWF BIII in the updated parameters will not have a significant negative impact on these benthic organisms.

The different types of potential impacts of offshore wind farms on the benthos that occur at successive stages of the project are presented mainly based on literature data in Chapter 7.

The most important impact on benthos during the construction phase is its physical destruction associated with the installation of wind turbine foundations and internal connection infrastructure. At the operational stage, an important factor that changes the nature of the habitat in the farm area is the "artificial reef" effect, i.e., the overgrowth of underwater structures of wind turbines by the epiphytic flora and fauna. At the decommissioning stage of the farm, the dismantling of these structures will result in the loss of this habitat.

The impact assessment included in the 2015 Report considered two project alternatives. In the case of the set of parameters of the Project constituting the most far-reaching NIS 2015 scenario, the maximum number of foundations possible in the BIII offshore wind farm area was taken into account, as well as the technical parameters of gravity foundations, whose footprint is much larger than that of the other types of foundations and can therefore have the most negative impact on the benthos. Thanks to such assumptions, the most far-reaching scenario of the project, the 2015 NIS, i.e. the one with the highest negative impact on the benthos, was evaluated. The variant of the Project in the parameters approved by the Environmental Decision will be more favorable to the benthos due to the fact of preserving a larger area of intact bottom structure and the habitats they inhabit. However, the values of physical destruction of benthos and loss of habitat in this variant compared to the alternative variant are only marginally lower, which does not change the significance of individual impacts. In the case of the proposed modification of the parameters of the Project, they are further reduced.

If the parameters of the project are modified, there will be a further reduction in the number of power plants, but also in the area occupied by foundations as a result of the exclusion of the possibility of using gravity-type and tripod foundations for the foundation of power plants and the limitation of the number of foundations for substations to 1 unit, and thus the changes in the ecosystem in the area of OWF BIII related to the creation of an "artificial reef" will cover an area even smaller than in the case of the Project in the parameters approved by the Environmental Decision. Any environmental interference that destroys the naturalness of the environment makes such an impact take on a negative character with unknown effects on the ecosystem in the long term.

The impact assessment was based on a sensitivity analysis of all 4 phytobenthic taxa found in the buffer zone of the BIII OWF, as well as 12 of the most common macrozoobenthic species that are part of two different communities: Mytilus trossulus and Pygospio elegans of the actual farm area including the buffer zone. Among the benthos, only one strictly protected species was found - the pitchfork Furcellaria lumbricalis - formerly F. fastigiata (in accordance with the Regulation of the Minister of Environment of October 9, 2014 on the protection of plant species (Journal of Laws 2014, item 1409). This kelp was attached to a colony of mussels on the sandy bottom. It can be assumed that it came from other areas than the IMF study area, as small aggregations of mussels can be carried by currents from place to place. The sensitivity of most benthic species was low or medium depending on the type of impact.

The most important cumulative impacts on benthos that may occur during the various stages of the project are the spreading of suspended solids due to the disturbance of the bottom sediment structure, which may then sink to the bottom even up to 20 km from the site of the construction works (and thus at the locations of other proposed farms), and the formation of an "artificial reef" on the underwater elements of several neighboring farms. Cumulative impacts are assessed as negligible or small.

On the basis of the screening conducted regarding the assessment of the project's impact on the integrity, coherence and subject of protection of Natura 2000 areas, it was concluded that no direct, indirect, secondary or cumulative impacts of the project on the benthos of the nearest areas are expected: Slupsk Shoal (PLC990001) and Baltic Coastal Waters (LB990002), located in the Natura 2000 network.

The analysis of associated impacts concluded that the loss of habitat as a result of the construction of the farm will be very small, and the depletion of the food base, which is benthos for seabirds and fish, will not be permanent. The introduction of hard substrate into the environment will produce an "artificial reef" effect, and the region around the foundations will become a place for concentration and feeding of many fish species.

Due to the distances to the EEZs of other countries (the closest one, the EEZ of Sweden, is about 50 km away) and the mostly local scale of impacts, the BIII OWF is not expected to cause transboundary impacts, i.e. to affect the benthos within the borders of other countries (including their exclusive economic zones), either alone or in cumulation.

Potentially, the most significant unplanned impact could be a larger oil spill resulting from an accident or collision. However, even in this case, its importance to the benthos is assessed as negligible or small.

A summary of the assessment of the impact of the project at the stage of construction, operation and decommissioning in the BIII OWF area, as well as the impact of the proposed changes in the parameters of the Project on the significance of the impact are presented in the tables below.

In all cases, the nature of the impacts, including cumulative impacts, is local. Taking into account that the magnitude of impacts is moderate to the highest degree, with low importance of phytobenthos and medium importance of both macrozoobenthos assemblages in the area of OWF BIII - the importance of all impacts at different stages of the project is negligible or low. In this case, minimization measures are not required.

Despite the low significance of the impact of OWF BIII on the benthos, monitoring is advisable due to the fact that this will be the first study of its kind in the Southern Baltic, verifying actual changes in the state of one of the components of the ecosystem. The results obtained during post-investment monitoring will ultimately determine the actual nature of the project's impact (positive or negative) during its operation phase.

15.1. Phytobenthos

Table 42 Assessment of the impact of the Project update on the results of the phytobenthos impact assessment in the most far-reaching scenario (NIS 2015) - construction phase

Impact	Importance of the resource	Minimization measures	Magnitude of impact	The significance of the impact	The impact of modifying the parameters of the Project on the significance of the impact

16. Shortcomings in technology and gaps in modern knowledge

No wind farm construction, operation or dismantling work has been carried out in the southern Baltic Sea to date. There are no results of studies on the impact of submerged elements of wind turbines on benthic assemblages (succession of overgrowth of newly introduced hard substrate, appearance of phytobenthic and zoobenthic growth species, local change in the qualitative and quantitative structure of the benthos). In part, the answer to the above problems can be found in the scientific literature documenting the results of research in the above-mentioned area conducted in other areas of the Baltic Sea. However, full information taking into account the specifics of the benthos of the eastern part of Slupsk Shoal will be provided by post-investment studies. Lack of data or limited knowledge about the impact of noise on benthos does not make it possible to confidently and unequivocally assess the impact of this factor. The effects of heat emission and electric field and radiation on benthos are very poorly documented in the literature to date.

Abbreviations and definitions

DSU	Decision on environmental conditions
Environmental Decision	Decision on environmental conditions issued by the Regional Director for Environmental Protection in Gdańsk on July 7, 2016, ref. No. RDOŚ-Gd-WOO.4211.12.2015.KP.22, for the project named "Construction of the Bałtyk Środkowy III Offshore Wind Farm"
Dispersion	Dispersion, spreading of suspended sediment in the water depths
HCB	Hexachlorobenzene
ICES	International Council for the Exploration of the Sea
EEZ	Exclusive Economic Zone (Exclusive Economic Zone)
EW	Wind power plant
HCB	Hexachlorobenzene
Ichthyofauna	Fish
HVDC cable	AC high voltage cable
l.t.	Total length of the fish (longitudo totalis)
Heavy metals	A group of metals characterized by high density and often toxicity
IMF	Offshore wind farm
IMF Baltica 2	Baltica 2 offshore wind farm
IMF Baltica 3	Offshore wind farm Baltica 3
OWF BIII/ Project	Bałtyk Środkowy III Offshore Wind Farm
IMF BSII	Offshore wind farm Baltic Central II/ Offshore wind farm Baltic II
NIS 2015	The most far-reaching scenario from the 2015 Report, which is a set of parameters of the project causing the most far-reaching impacts, and which was the basis for conducting an environmental impact assessment during the proceedings that ended with the issuance of the Environmental Decision.
EIA	Environmental impact assessment
PCB	Polychlorinated biphenyls
PGE	Polish Energy Group
POM	Polish maritime areas
PSZW	Permit for the erection and use of artificial islands, structures and devices in Polish maritime areas dated 30/03/2012 No. MFW/2/2012 ("PSZW") with a maximum capacity of 1200 MW and a maximum number of 200 power plants
PTS	Permanent shift in hearing/hearing threshold (=TPPS)
Report/EIA Report	Environmental impact report
Resuspension	Re-precipitation, disturbance of sediments deposited on the bottom of the reservoir, caused, for example, by wave action, net dragging. It can be an internal source of enrichment of the water tone with nutrients (biogenic) accumulated in sediments.
Report 2015	The Environmental Impact Assessment Report for the purposes of the procedure finalized by the decision of the Regional Directorate for

	Environmental Protection dated July 7, 2016, ref. No. RDOŚ-Gd-WOO.4211.12.2015.KP.22
ROV	Remotely Operated Vehicle (Remotely Operated Vehicle)
SL	Standard length of fish (standard length)
SPL	Sound pressure level
ΣDDT	The sum of DDT (dichlorodiphenyltrichloroethane) and its derivatives; most often the sum includes 3 compounds: • pp'-DDT - 1,1,1-trichloro-2,2-bis(4-chlorophenyl)ethane, • pp'-DDD - 1,1-dichloro-2,2-bis(4-chlorophenyl)ethane • pp'-DDE - 1,1-trichloro-2,2-bis(4-chlorophenyl)ethylene
PCDD/F	A group of compounds (often referred to as dioxins) that consist of: • PCDD -polychlorinated dibenzodioxins • PCDF - polychlorinated dibenzofurans
TBT	Tributyltin
TSS	Traffic Separation Scheme
TTS	Temporal shift of hearing/hearing threshold (=CPPS)
WWA	Polycyclic aromatic hydrocarbons

1. Non-specialist summary

A non-specialist summary of the results of the assessment of the impact on ichthyofauna of the changes proposed to be made to OWF BIII, for which the Environmental Decision was issued, is included in Section 5.2 of Volume VI of the Report.

2. Introduction

This section analyzes the potential impacts of changing and updating the Project's implementation and operation conditions on fish (ichthyofauna). The EIA Report includes an analysis of whether the requested changes made against the provisions of the RDOŚ decision of July 7, 2016, marked RDOŚ-Gd-WOO.4211.12.2015.KP.22 (zpo) result firstly in a change in the potential impacts determined for OWF BIII on fish (ichthyofauna), as well as secondly whether there is a need to adjust other conditions of the project behind the introduced changes.

This section is based on the research and analysis and findings made for the impact assessment made in the 2015 Report taking into account changes in the legal status and available environmental information that emerged after the date of the 2015 Report. At the same time, it should be noted that the data on which the 2015 Report is based remains valid for the variant indicated for implementation under the Environmental Decision. In the case of the modified parameters proposed for implementation on the basis of an amendment to the Environmental Decision, they should also be considered adequate, which is due to the fact that the scale of the planned Project changes, where its parameters related to the number of wind power plants are reduced by 50% in relation to the Environmental Decision, a decisive part of the parameters remain the same, and some of the parameters specified as possible in the Environmental Decision are clarified, such as the method of foundation of the power plant foundations. On the other hand, the parameters that increase, such as the maximum height of the power plant and the maximum diameter of the rotor, are not parameters whose change can generate a change in terms of impacts on ichthyofauna.

Analyses made in this EIA Report are based on research conducted by the Maritime Institute of Fisheries - National Research Institute on behalf of the Maritime Institute in Gdansk, in the area of OWF BIII and in the buffer around its borders, which formed the basis for obtaining a decision on environmental conditions. The results of the research were reviewed and evaluated in the context of the scope of the changes planned to be made in the RDEP's decision dated July 7, 2016, marked RDOŚ-Gd-WOO.4211.12.2015.KP.22.

3. Description of the planned project

The parameters of the BIII OWF that are relevant to the assessment of the project's impact on ichthyofauna are:

- farm location;
- area of the farm - total and buildable;
- foundations - types, number, dimensions, method of foundation and the seabed area occupied by them;
- power cables - their length and the surface of the bottom disturbed during their laying.

The characteristics of the Project, including information relating to its construction, operation and decommissioning phases, are presented and characterized in terms of potential emissions and environmental disturbances in Volume II of the Report.

3.1. Basic parameters of the project

Currently, the project planned for implementation is defined by the decision of the RDOŚ dated July 7, 2016, marked RDOŚ-Gd-WOO.4211.12.2015.KP.22. With regard to the conditions of implementation of the Project specified in the EIA, the key parameters of the Project, which were the source of impacts on ichthyofauna, were significantly reduced. The plant's foundation technology has also been concretized.

Table 1. Technical parameters of the BIII OWF relevant to the assessment of the impact on fish

Parameter	Parameters of the Project approved by the Environmental Decision	Parameters of the Project after the proposed modifications
Maximum number of power plants [pcs.]	120	60
Maximum number of substations [units]	6	1
Maximum length of power cable sections [km]	200 km	200 km
Maximum cable trench width [m]	1,5 m	1,5 m
Maximum/average cable trench depth [m]	3 m / 1.5 m	3 m / 1.5 m
Types of power plant foundations considered	monopile, tripod type, jacket type (truss) and gravity	monopile and jacket (truss) type
Considered types of supporting infrastructure foundations	monopile, tripod type, jacket type (truss) and gravity	monopile, tripod type, jacket type (truss) and gravity
Gravity foundation: 1. Base diameter (max) 2. The diameter to which the bottom is dredged (max) 3. Depth to which the bottom is dredged (max) 4. Width of leaching protection layer from the foundation perimeter (¶) 5. Depth of the protective layer against leaching (¶) Foundation column diameter (max)	1. 50 m 2. 70 m 3. 3 m 4. 15 m 5. 1,5 m 6. 6. 7,5 m	1. 50 m 2. 70 m 3. 3 m 4. 15 m 5. 1,5 m 6. 6. 7,5 m

Parameter	Parameters of the Project approved by the Environmental Decision	Parameters of the Project after the proposed modifications
Steel monopile foundation: 1. Diameter (max) 2. Length (max) 3. Width of leaching protection layer calculated from the foundation perimeter (¶) 4. Depth of the protective layer against leaching (¶) 5. Air hammer energy (max)	1. 12,5 m 2. 120 m 3. 20 m 4. 1,5 m 5. 3000 kJ	1. 10 m 2. 120 m 3. 25 m 4. 1,5 m 5. 4500 kJ
Jacket type foundation: 1. Distance between foundation legs (max) 2. Number of foundation legs (max) 3. Diameter of foundation legs (max) 4. Pile diameter (max) 5. Pile length (max) 6. Width of leaching protection layer calculated from the edge of a single pile (max) 7. Depth of the protective layer against leaching (¶) 8. Air hammer energy (max)	1. 40 m 2. 4 pcs. 3. 3 m 4. 3 m 5. 70 m 6. 10 m 7. 1,5 m 8. 2300 kJ	1. 40 m 2. 4 pcs. 3. 3 m 4. 3 m 5. 70 m 6. 10 m 7. 1,5 m 8. 2300 kJ
Tripod type foundation: 1. Distance between foundation legs (max) 2. Number of foundation legs (max) 3. Diameter of the main foundation column (max) 4. Diameter of side pipes (max) 5. Pile diameter (max) 6. Pile length (max) 7. Width of leaching protection layer	1. 40 m 2. 3 pcs. 3. 7 m 4. 5 m 5. 2,5 m 6. 60 m 7. 10 m 8. 1,5 m 9. 2800 kJ	1. 40 m 2. 3 pcs. 3. 7 m 4. 5 m 5. 2,5 m 6. 60 m 7. 10 m 8. 1,5 m 9. 2300 kJ

Parameter	Parameters of the Project approved by the Environmental Decision	Parameters of the Project after the proposed modifications
calculated from the edge of a single pile (¶) 8. Depth of the protective layer against leaching (¶) 9. Air hammer energy (max)		

Source: Own elaboration based on Offshore wind farm Baltic Central III. Environmental impact report, SMDI Doradztwo Inwestycyjne Sp. z o.o. 2015

With regard to the above information, it should be noted that for wind power plants only monopile and jacket (truss) type foundations are currently considered, the implementation of which is assumed as possible and, in principle, applicable in the absence of technical feasibility of monopile foundations, while the possibility of founding power plants on gravity and tripod type foundations has been excluded. In the case of a substation, monopile, tripod, jacket (truss) and gravity type foundations are considered for its foundation, while the number of substations has been reduced from 6 to 1 unit.

3.2. Projects whose impacts may cumulate with the impacts of the OWF BIII on fish

There are other projects planned in the project area that could potentially, along with the BIII OWF, cause cumulative environmental impacts. At the outset, however, it should be noted that key to their evaluation is the fact that the scope of the Project has been reduced by reducing the number of wind turbines planned to be built under it by 50%.

At the beginning of this chapter, it is necessary to clarify how cumulative impacts are understood in the report. Three types of it can be distinguished:

1) the cumulation of the same impacts within the BIII OWF,

2) accumulation of various impacts within the BIII OWF,

3) the cumulation of the same or different impacts of the BIII OWF and other projects.

An example of the cumulation of the same impacts within a project could be the simultaneous disturbance of the bottom sediment structure by a dredge that may be working to prepare the bottom for a gravity foundation. However, as a result of the modification of the parameters of the Project, such a situation has been eliminated due to the limitation of the possibility of using gravity foundations for substations of 1 unit.

Nevertheless, the above assumption was adopted as the maximum in the suspended solids spread model for the project alternatives under consideration (Volume II Section 11 of the 2015 Report), and thus - used in all assessments where suspended solids spread is relevant, both abiotic and biotic. At this point, it should be noted that the fact of abandoning gravity foundations for wind turbines will significantly reduce this type of impact and the possibility of its cumulation with other projects.

As an example of the accumulation of various impacts within the BIII OWF, implemented with the proposed changes in mind, the laying of power cables by a cable carrier can still be cited. This is an unlikely scenario, but was included as part of the evaluation for the option selected for implementation.

Meanwhile, the third type of accumulation is devoted to this chapter and the "assessment" chapters - 9.1.6 (construction phase), 9.2.6 (operation phase), 9.3.5 (decommissioning phase) and 11.6

(unplanned impacts). These chapters assess the potential cumulative impacts on the fish of the BIII OWF and other projects located or planned in the vicinity of the planned farm and listed in this chapter. These included offshore wind farms and transmission infrastructure.

It should be noted that these projects are concentrated to the east of Slupsk Shoal for other wind power plants and to the south for and north for transmission infrastructure.

For the purposes of this report, projects that have the potential to generate cumulative impacts on fish have been identified. The potential impacts of these investments are mainly the possibility of cumulative growth of suspended solids in the water body, release of toxic substances and noise emissions (construction of the OWF and foundation of transmission cables), emission of electromagnetic fields (existing and planned power cables) in case the above-mentioned investments are implemented at the same time.

A list of projects whose environmental impacts may cumulate with those of OWF BIII, along with the rationale for their selection, is presented in Section 13 of Volume II of the Report. For the purposes of this study, they are presented in the tables below. As indicated in the aforementioned section of this report, offshore wind farms located in Zone 1, i.e. located between 1 and 150 km from the Project, were considered for cumulative impacts.

Table 2. List of offshore wind farms with which the impacts of the BS III OWF on fish may cumulate

Lp.	Type and name of the project	Distance from IMF BIII	Basic parameters, relevant to the assessment of cumulative impacts	Status
1	IMF BSII	a minimum of about 17 km, in a northwest direction	60 wind power plants, expected completion date 2025-28	The project has a DSU (with its amendment), connection conditions and connection agreement
2	IMF Baltica (Baltica 2 and Baltica 3)	in the immediate vicinity of Baltica 3 to the north, Baltica 2 to the northwest	90 Baltica 3 wind turbines, 119 Baltica 2 wind turbines, expected completion date Baltica 3 2025-28	Projected investment - PSZW issued and paid for; Project has DSU: The project has connection conditions and a connection agreement for up to 1.045 GW (1,045 MW) of power in the Baltica 3 range
3	FEW Baltic II	a minimum of about 30 km, in the northwest direction	44 wind power plants, expected completion date 2028-30	Projected development - PSZW issued and paid for; Project has DSUs
4	Baltic Power	approx. 3 km, in an easterly direction	126 wind power plants, expected completion date 2028-30	Projected investment - PSZW issued and paid for; Investment at the stage of obtaining DSUs

Lp.	Type and name of the project	Distance from IMF BIII	Basic parameters, relevant to the assessment of cumulative impacts	Status
5.	C-Wind	Approximately 20 km in an easterly direction	41 wind power plants, expected completion date 2028-30	Projected investment - PSZW issued and paid for; Investment at the stage of obtaining DSUs

With regard to the information contained in the 2015 Report, it should be noted that a significant reduction in the risk and possible scale of cumulative impacts, in addition to the reduction in the number of wind power plants implemented as part of the Project, is influenced by the issue of expiration of licenses for oil or gas exploration and prospecting. Following the information published on the website of the Ministry of Climate[1], it is to be assumed that no concessions are currently in force in the area in question.

4. Existing anthropogenic pressures

Fishing has been identified as the main anthropogenic pressure affecting ichthyofauna in the area of the proposed OWF BIII .

In order to determine with as much accuracy as possible the impact of the investment on fisheries (to determine potential losses of fisheries) in the area occupied by the BIII OWF (in the case of the most far-reaching scenario of complete exclusion of the farm area from the possibility of fishing), the relative share of the area that the farm will occupy in relation to the total area of fishing squares was taken into

[1]https://bip.mos.gov.pl/koncesje-geologiczne/raporty-i-zestawienia-dotyczace-udzielonych-koncesji-w-tym-zestawienia-otworow-wiertniczych/raporty-i-zestawienia-rok-2022/raporty-i-zestawienia-marzec-2022-r/

account. The area of OWF BIII is about 119 square kilometers, while the area of fishing squares M7, M8, N7, N8, on parts of which the farm will be located, is 1.58 thousand square kilometers. Thus, IMF BIII occupies about 7% of the total area of the four quadrants.

A detailed description of fisheries is presented in the study "Monitoring of fisheries in the area of the offshore wind farm Central Baltic III. Final Report with Study Results" (Volume III Section 13 of the EIA).

Other existing anthropogenic pressures have a very low impact on ichthyofauna (sea angling, underwater tourism, noise and vibration from ship traffic, climate change).

Current data on the distribution of the fishing fleet shows that the study area is unlikely to be a place of particular interest to anglers because of the economic calculus, which generally allows for fishing in a zone up to 10 Mm from shore.

Humans are influencing global warming with their impact on the environment. The effects of this phenomenon will also be felt in the future on the water body in question. They will most likely be reflected in the salinity and temperature of the seawater. Mathematical models are used to predict the extent of these changes (Meier et al., 2012; Neumann, 2010). Such predictions were published by HELCOM in "Climate change in the Baltic Sea Area HELCOM thematic assessment in 2013." The cited models and discussions forecast changes through the end of the 21st century. Analyzing the results and maps there, it can be assumed that the surface water temperature in the basin in question will increase by about 2 °C by the end of the century. Salinity, on the other hand, will drop by about 1.5 to 2 PSU during the period. However, it is important to remember that it is difficult to predict all possible scenarios. This is especially true for salinity, the changes of which will depend on the difference in freshwater supply to the sea (from rivers and precipitation) and evaporation. However, assuming the extent of the changes that are predicted by the end of this century, it can be assumed that they will not drastically affect fish stocks over the expected lifetime of the wind turbines.

These findings are consistent with those made at the stage of issuing the Environmental Decision. This is due to the fact that the pressure on ichthyofauna has not changed, and in addition, the proposed changes to the Project significantly reduce the number of power plants to be built.

5. Description of the anticipated effects on the environment if the project is not undertaken

This chapter analyzes the effects on ichthyofauna in the case of not undertaking the project, which would entail the decision to abandon the Project in the shape and scope specified both in the Environmental Decision), as well as in the scope covered by the application to amend the above-mentioned decision.

In doing so, three scenarios were considered

- offshore wind energy will not be developed in the Polish maritime areas, and therefore the evaluated BIII OWF project, or similar ones, will not be implemented,
- offshore wind energy will be developed in the Polish maritime areas, but the assessed project - BIII OWF - will not be implemented,
- in Polish maritime areas, investments in offshore wind power are not being made, but the mining industry is developing.

The results of the analysis are shown in the table below.

Table 4. Effects on ichthyofauna if the project is not undertaken

Lp.	Script	Environmental implications
1.	Offshore wind energy will not be developed	No action related to the construction, operation or decommissioning of offshore wind farms would mean no impact on fish. So, on a short-term scale, the ichthyofauna will remain in its current ecological state. The area designated for OWF BIII will remain unchanged and will continue to be used as before (no change in the structure of the bottom surface, no navigational impediments, a larger fishing area). However, changes in the amount of fishing pressure on the area, caused by the dynamics of the size of Baltic fish stocks, are possible. In the analyzed area, as a result of the normal operation of ships, spills of various types of substances (diesel and lubricating oils, gasoline, etc.) may enter the water depths in small quantities, causing deterioration of water quality and sediments, and indirectly - fish living conditions. An indirect considered impact of placing power plant foundations on the bottom is the creation of new habitats (the "artificial reef" effect). This effect will increase the abundance and biomass of fish living within the structures, as a result of a kind of "diversification" of the homogeneous underwater environment of the southern Baltic. If the investment is abandoned, this effect will not occur. A detailed description of the status quo can be found in the study "Monitoring of ichthyofauna of the area of the offshore wind farm Central Baltic III. Final Report with Study Results" (Volume III Section 7 of the EIA).
2.	Offshore wind energy will be developed, but OWF BIII will not be realized	In the event that the BIII OWF is not built, but other wind farms are built in neighboring locations as a result of offshore wind energy development, no significant impact on fish is expected in the BIII OWF area. Only the suspended solids that will rise during the construction of these farms may settle in a small layer on the

Lp.	Script	Environmental implications
		seabed. In addition, noise impacts may be important if foundation piles are driven. However, it should be assumed that mitigation measures will be applied, for example, in the form of bubble curtains, which will significantly reduce the scale of noise. From the point of view of impacts on fish, the type of sediment present at the planned OWF site will be important. A greater impact involving the redistribution of pollutants deposited in the sediments into the water body and the formation of greater long-lived suspended solids will be observed for clay sediments (with a high content of organic matter and fine fractions), which are generally characterized by higher contents of metals, nutrients and organic pollutants. There will be less impact when offshore wind farms are located in the area of coarse sands (with low organic matter and fine fractions), which are characterized by a low content of metals, nutrients and organic pollutants. The area allocated for OWF BIII will remain unchanged and continue to be used as before.
3.	Offshore wind power will not develop, but mining industry will grow	Potential impacts on the ichthyofauna of the BIII offshore wind farm area may also result from other uses of marine resources in its immediate vicinity, such as aggregate extraction from the seabed or oil/gas extraction. Impacts will be similar to those of wind farm construction.

6. Impact assessment methodology

The project's impact assessment was carried out in accordance with the project's framework methodology, as described in Section 5 of Volume I of the report, with some modifications or refinements, as discussed below.

6.1. Modifications or refinements to the evaluation framework methodology

The study makes the following modifications or refinements to the evaluation framework methodology. Chapter 8 defines the degrees of vulnerability (sensitivity) of selected species to the potential impacts of the wind farm. The assessment of species sensitivity was then used to categorize impact intensity in the "Impact Magnitude Assessment Matrix."

For the exposure scale classification, the generally accepted rules for Baltic fish stock classification and the zonality of the POM were followed (Figure 4 below):

- local - impact on populations in the area of OWF BIII,
- regional - impact on populations in the area of ICES zone 25 of the Polish Maritime Areas,
- national - impact on populations in the POM region,
- international - impact on populations/stocks in the Baltic Sea.

Figure 2 shows the boundaries of the marine area zones. The blue line marks the boundaries of the countries' economic zones, while the red line marks the boundaries of ICES sub-areas.

The aspect of the scale of exposure has the greatest impact on the result of the "Impact Magnitude Assessment Matrix."

For fish stocks, stocks are classified by definition as a collection of fish of a given species with a temporally and spatially unique migratory cycle. The herd is homogeneous internally through excellent mixing of the gene pool. ICES currently classifies stocks in the Baltic Sea as follows:

- cod - two stocks (22-24 and 25-32),
- herring - four stocks (22-24, 25-29, herring of the Gulf of Riga and the Gulf of Bothnia),
- sprat - one stock,
- flounder - one flock (22-32),
- salmon - two stocks (22-31 and 32),

- the remaining species belong to a single stock.

The above classification is crucial in determining the scale of impact, and a large territorial range of fish stocks is implied.

6.2. The most far-reaching scenario of the venture - NIS 2015

The initial EIA, which formed the basis for the issuance of the Environmental Decision, was conducted on the basis of indicating the assumptions for the Project, as well as by identifying the investment scenario that could potentially have the greatest impact on fish, among others. Thus, the assessment was carried out based on the concept of the envelope, i.e., determining the set of parameters of the Project that generate the most far-reaching impacts called the furthest-reaching scenario - NIS 2015, and subjecting such theoretical shape of the Project to an impact assessment. The furthest-reaching scenario - the 2015 NIS - then provided a benchmark for assessing whether the planned Project as proposed and submitted for implementation based on the 2015 Report is acceptable, or, alternatively, what conditions must be introduced for the furthest-reaching NIS 2015 scenario so that the impacts generated by the Project are not significantly negative impacts. These verified and limited to the thresholds of safe and environmentally acceptable conditions for the implementation of the Project were specified by the authority in the Environmental Decision. Thus, at this stage, the conditions set forth in the Environmental Decision have become the most far-reaching scenario of acceptable impacts of the Project. In each case, it is the conditions set forth in the Environmental Decision that are the benchmark for evaluating the changes proposed in this proceeding. It should be noted that the purpose of the current impact assessment is to verify and characterize the current impacts of the Project in connection with the further development of the project, as well as to carry out amendments to the Environmental Decision resulting from the progress of work and the reduction of the scope of the Project and the introduction of additional measures to reduce its impact in relation to those envisaged at the stage of issuing the Environmental Decision. However, since the impact assessment contained in the 2015 Report is based on an assessment of the impact of parameters that may cause the most far-reaching impact scenarios, in conducting this impact assessment of the proposed amendments to the Environmental Decision and the concretization of the parameters of the Project, it is necessary not only to refer to the conditions set forth in the Environmental Decision itself, which currently set the rules for the implementation of the Project and constitute its alternative to the Project to be implemented after the amendment of the Environmental Decision, but also to the most far-reaching scenario adopted in the 2015 Report (NIS 2015), as this one set the most far-reaching limiting parameters of the Project, the implementation of which did not cause significant negative environmental impacts.

With the above in mind, it should be pointed out that at the stage of the 2015 Report, it was considered that the set of parameters of the Project - NIS 2015 would occur in the variant, which was to consist in the construction of 200 wind power plants with accompanying infrastructure (including 7 offshore substations and 1 add-on foundation) on gravity or monopile foundations, i.e. the maximum number of power plants allowed to be installed in the area of OWF BIII according to the location decision (PSZW).

At the stage of the 2015 Report, gravity foundations were considered for the foundation of both the wind turbines themselves and the associated infrastructure elements. This solution has the largest base diameter and area of all those considered at the time. Gravity foundations also require bottom preparation, and thus their foundation causes the greatest impacts related to habitat alteration, suspended solids spreading or release of toxic substances from sediments. Currently, the use of this type of foundation has been ruled out against wind power plants. On the other hand, it should be pointed out that a gravity-type foundation has not been ruled out as possible for the foundation of a substation. The very fact that gravity foundations are excluded from use for wind power plants, with this type of foundation allowed only for the substation, is to be confirmed by the change in the conditions for implementation of the Project by specifying in the decision amending the Environmental

Decision that monopile and jacket type foundations will be used for the Project, and for the substation all types of foundations considered so far, including gravity foundations, may be used.

In contrast, potentially the greatest noise occurred when monopile foundations were driven into the seabed.

The variant selected for implementation and indicated in the Environmental Decision consists of up to 120 power plants, i.e. about 40% less than in the 2015 NIS. The above indicates that the option selected for implementation and determined by the Environmental Decision will cause environmental impacts equal to or less than the one considered in the 2015 NIS.

Referring to the above conclusions, therefore, it should be pointed out that the currently proposed change leads to a reduction in the number of power plants to 60, which is about 70% (70.68%) less than in the 2015 Report's analysis of the Project's parameters constituting the 2015 NIS, and 50% less than in the variant indicated for implementation in the current Environmental Decision.

These circumstances indicate that the impact of the Project in the shape and scope to be determined by the requested amendment decision will be significantly less than that which was subjected to the original environmental impact assessment

7. Potential impacts of offshore wind farms

Knowledge of the IMF's impact on ichthyofauna is limited. Planning and building OWFs is a relatively new industry, so only a few studies have been conducted directly on OWFs so far. Earlier studies focus on examining the impact of individual turbines that were much smaller than those currently planned and constructed (Smith and Westerberg, 2003). Moreover, they can only be partially applied to the planned project due to the fact that they concerned bodies of water with different characteristics than the South Baltic (differences in biodiversity, substrate structure, lack of tidal incidence, etc.).

Studies conducted at the Horns Rev wind farm (Denmark) have shown no or negligible impact (depending on the factor studied) of the investment on fish, no significant differences in benthic assemblages, and the emergence of epiphytic assemblages - the basis of the "artificial reef" ecosystem (Elsam Engineering A/S, 2005; Leonhard et al., 2011). Similarly, studies at the Burbo Offshore (England) have shown no or low impact on birds and negligible impact on the other environmental elements studied (SeaScape Enerdy Ltd., 2002). The types of impacts are shown in the table below.

Table 5. The main sources of impacts at different stages of the OWF's existence

Type of impacts	Phase		
	Construction	Operations	Liquidation
Noise and vibration	x	x	x
Sediment suspension	x		x
Electromagnetic field		x	
Water pollution	x		x
Habitat changes	x	x	x

Source: Nermer T., Drgas A., Janusz J., et al. "Monitoring of ichthyofauna of the area of the offshore wind farm Central Baltic III. Final Report with Impact Assessment," Marine Fisheries Institute - National Research Institute, Gdynia, 2015, based on Spanggaard G. 2006, modified

In addition, unplanned emissions may occur at any stage of the project, such as explosions associated with bottom clearing of UXO, contamination of the water tone and bottom sediments with petroleum substances (during normal operation and in an emergency), antifouling agents, accidentally released municipal waste or domestic sewage, chemicals, and waste from the construction, operation or decommissioning of the farm. They will indirectly affect living organisms, including fish. An assessment of the impacts of unplanned events on ichthyofauna is presented in Chapter 11 of this document.

7.1. Construction phase

7.1.1. Increase in the concentration of suspended solids in water

During preparatory work and during the construction of offshore wind farms, the sediment layer is disturbed, which is associated with the floating of sediment particles into the water depths. Wind farms, for technological reasons, are most often planned in bottom areas covered with sandy and gravelly sediments. The relatively high specific gravity of sediment particles causes them to sink to the bottom relatively quickly after they have risen in the water's depths. This indicates a rather local and short-lived (largely limited to the duration of the works) increase in suspended solids in the water tone.

The significance of a suspension's effect on ichthyofauna depends on a number of factors related to the characteristics of the suspension's particles, including density, size distribution and particle shape, the particles' ability to adsorb and absorb, and their mineral composition. Environmental conditions, such as temperature or oxygen concentration in the overdraft water, can also play an important role (Hygum, 1993, after Engell-Sorensen and Skyt, 2001). At the same time, the higher the concentration of suspended sediment and the longer the exposure time, the greater the negative impact on marine organisms (Newcombe and MacDonald, 1991).

A very important factor determining the intensity of the impact of the suspension on ichthyofauna is what developmental stage the analyzed individuals are in. The most sensitive stage of fish development is the larval period. Unlike adults, larvae are characterized by a limited ability to move and, consequently, to escape adverse environmental conditions (Knudsen et al., 1992; Wahlberg and Westerberg, 2005). While for juvenile and adult fish the lethal effects of suspension can be expected at concentrations on the order of grams/liter, for earlier life stages (eggs and larvae) concentrations on the order of milligrams/liter can already be dangerous (Engell-Sørensen and Skyt, 2001).

The level of impact of the suspension on larvae and eggs depends on both the characteristics of the suspension and the age, morphological characteristics and species of larvae and eggs.

The larvae have high oxygen requirements associated with rapid metabolism and higher oxygen consumption relative to body weight (Auld and Schubel, 1978; Partridge and Michael, 2010), making them particularly vulnerable to respiratory obstruction. The adherence of suspended particles to the gills of larvae can therefore cause increased mortality (Groot, 1980).

Another mechanism for the suspension's effect on larvae is to reduce visibility. Most larvae use their eyesight to search for food, with herring (Batty, 1987; Boehlert and Morgan, 1985), flatfish and cod larvae seeing from a distance of only a few millimeters, which is less than their body length (Bone et al., 1987). Since larvae are unable to survive prolonged periods of starvation, difficulties in acquiring food quickly result in increased mortality. The effect of the suspension on the ability to see food particles depends on both the concentration of the suspension and the developmental stage/age of the larvae.

There is evidence that moderate water turbidity (35 JTU- *Jackson Turbidity Unit*) may benefit the ability of smaller (20 mm) Atlantic herring larvae to acquire food (Utne- Palm, 2004; Boehlrt and Morgan, 1985). A possible explanation for this phenomenon is that the increased amount of suspended matter

in the water tone improves the contrast between food and background (Hinshaw, 1985). Particles of suspended matter scatter light, making food less transparent and easier to see (Boehlert and Morgan, 1985).

High turbidity (80 IUU), on the other hand, negatively affects the ability of herring larvae across the size spectrum to acquire food (Utne-Palm, 2004; Chesney, 1989; Boehlrt and Morgan, 1985). Also, a study by Johnston and Wildish (1982) showed that a significant effect of reduced visibility on the decrease in the amount of food eaten by herring larvae was observed at a suspended solids concentration of 20 mg dry sediment/l, with smaller larvae being most affected. A similar effect was observed by Boehlert and Morgan (1985) for Pacific herring*(Clupea harengus pallasi*) larvae at a dose of 2,000 mg/l for 24 hours. Increased water turbidity also reduces the ability of flat fish larvae to see food (Boehlrt and Morgan, 1985 after Moore & Moore, 1976). Less food intake can translate into slower growth rates.

Increased turbidity due to increased suspended solids may also indirectly positively affect larval survival by reducing predation pressure associated with reduced visibility (Gregory and Northcote, 1993). At the same time, reducing this pressure makes the larvae more active - they swim longer and more often (Utne-Palm and Stiansen, 2002).

The susceptibility of larvae to the effects of suspension depends on the developmental stage/age of the larvae, with most data available in the literature indicating that younger individuals are more sensitive. Studies of cod larvae have shown, at a suspension concentration of 10 mg/l, higher mortality of larvae with yolk sacs than for larvae after sac resorption (Rönnbäck & Westerberg, 1996).

Also according to Johnston & Wildish (1982), the adverse effect of suspension on the amount of food eaten is greater for small larvae.

As already mentioned, the effect of the suspension's effect on larvae is largely dependent on its concentration.

At concentrations of 3 mg/l, this effect for herring and cod larvae amounted to an avoidance response, while concentrations of 10 mg/l resulted in a noticeable increase in mortality of cod larvae at the gall stage (Westerberg et al., 1996). Also, the study by Messieh et al. (1981) showed variation in the response of herring larvae depending on the content of suspended solids in the water tone. At a concentration of 540 mg/l, smaller sizes of reared larvae were found (Messieh et al., 1981), while the effect of a suspension at a concentration of 2000 mg/l for a period of 24 hours resulted in a decrease in food consumption (Boehlert and Morgan, 1985). Exposure of larvae to the suspension at a concentration of 19,000 mg/l for 48 hours resulted in 100% mortality (Messieh et al., 1981). A slight increase in mortality (6%) already at concentrations of 25 mg/l was also observed for Siberian grayling (Thymallus arcticus), while at suspension contents exceeding 230 mg/l the mortality of larvae of this species after 4 days of exposure was 47% (Newcombe & MacDonald, 1991). A compilation of findings by Hanson (1995) indicates that increased mortality typically occurs at suspended solids concentrations exceeding 100 mg/L.

Increased suspended solids can have a direct negative impact on egg development and survival. The adherence of suspended particles to the egg shell results in obstruction of gas exchange and inability to get rid of harmful metabolites (Chapman, 1988; Argent and Flebbe, 1999; Kiorboe et al., 1981). A study by Rönnbäck and Westerberg (1996) showed a significant increase in mortality of cod larvae at suspended solids concentrations exceeding 10 mg/L.

The suspension also indirectly affects the survival and condition of pelagic eggs by reducing their buoyancy. This causes the eggs to sink to deeper water layers or to the bottom, where they are exposed to less favorable conditions (benthic predation, mechanical or physiological stress, deterioration of oxygen conditions). It has been found that, sinking of pelagic cod eggs, can already occur at a suspension concentration of 5 mg/l and an exposure time of 11 hours, and an increase in this concentration and

exposure time increase the rate of the sinking process (Rönnbäck and Westerberg, 1996). Demersal eggs are also adversely affected by increased concentrations of suspended solids. The results showed that covering Atlantic herring (Culepea harengus) eggs with a thin layer of sediment increases mortality, but there is no evidence of a direct negative effect of a suspension with a concentration of up to 7,000 mg/L (Messieh et al., 1981). There was also no negative effect on the development of herring eggs of a suspension at a concentration of 300-500 mg/L acting for one day. Also, suspended solids concentrations of 5- 300 mg/l sustained for 10 days did not adversely affect the development of Atlantic herring eggs (Kiorboe et al., 1981). However, according to the authors of this study, the sensitivity of eggs to increased suspended solids in the water depths may be higher when oxygen conditions deteriorate.

Studies on the effects of increased concentrations of suspension on demersal eggs of freshwater and estuarine fish conducted in the Chesapeake Bay region (USA) have shown a wide variability of responses in different species. For some taxa, a reaction was observed as low as 100mg/l (exposure time of 96 hours), while for other species no significant effect of the suspension on egg development was found even at concentrations exceeding 1000 mg/l (Auld & Schubel, 1978).

Long-term increased suspended solids in the water depths can have particularly adverse effects on demersal eggs of fish characterized by long embryonic development. In the case of salmonids, long exposure (72 days) to relatively low concentrations of suspended solids (157 mg/l) results in 100% egg mortality. Equally high mortality of rainbow trout eggs was observed as a result of six days of exposure of eggs to suspended solids concentrations in the range of 1000-2500 mg/l (Newcombe & MacDonald, 1991). Changing the structure of herring spawning substrate can affect the subsequent stock structure, as fish spawn in poorer environmental conditions due to the inability to find a suitable spawning site (Groot, 1980; Marschal and Crowder, 1996).

Studies of the effects of high concentrations of suspended matter on older stages of ichthyofauna reveal a number of potentially harmful impacts. Adverse effects have been found on the locomotor abilities of fish (Robertson et al., 2006), reduced fish growth (Robertson et al., 2006), and increased mortality, e.g. due to gill plugging (Bruton, 1985). The latter effect, in particular, can have a significant negative impact. Clogging the gills with suspended solids impedes gas exchange; larger particles become trapped in the gill lamellae impeding water flow, resulting in oxygen deficiency (DOER, 2000). This phenomenon is more severe for smaller fish both because of their greater oxygen requirements due to their faster metabolism and the smaller gill openings through which water flows (Moore, 1991). The magnitude of the impact of increased suspended solids concentration may also be the result of differences in lifestyle and gill morphology. For plankton-eating fish, such as herring, gills are much more likely to be clogged than in predatory fish.

The reduction in visibility caused by an increase in suspended solids concentration to 2000-3000 mg/l can also affect the ability of predatory fish to obtain food (McLeay et al, 1984, 1987; Redding et al, 1987; Reynolds et al, 1989) and limit their growth (Sigler et al, 1984). Abrasion of the body shell, abrasion of the protective mucus, increased susceptibility to parasites (Everhart and Durchow, 1970; Johnston and Wildish, 1981), and reduced resistance to disease in fish have also been found (Herbert and Merkens, 1961; Redding et al., 1987; Robertson et al., 2006).

Instances of physiological sublethal responses of fish to suspended matter have also been reported, such as elevated blood sugar and cortisol levels (Sigler et al, 1984; Servizi and Martens, 1987, 1992; Redding et al, 1987; Lake and Hinch, 1999); increased cardiac minute capacity (with suspended matter around 3300 mg/L, Bunt et al, 2004); increased ventilation rate (Horkel and Pearson, 1976; Berg and Northcote, 1985; Servizi and Martens, 1987); gill damage (Sigler et al, 1984; Servizi and Martens, 1987; Bergstedt and Bergersen, 1997; Lake and Hinch, 1999).

Threshold concentrations of suspended solids, which have the effect of avoiding polluted regions, vary depending on the species and life stage of the fish. In the case of juvenile forms of herring, the avoidance

effect was induced by a suspended solids concentration of 12 mg/l (Messieh et al., 1981), and in the case of adult fish 10 mg/l (Johnston and Wildish, 1981), 22 mg/l in adult smelt (Wildish and Power, 1985). Experimental studies have shown that concentrations of about 3 mg/l of lime and clay cause partial avoidance of the area by herring and cod, and 6-8 mg/l cause complete avoidance (Westerberg et al., 1996). Exposure of plaice to a suspended solids concentration of 3,000 mg/l for 14 days is lethal (Newton, 1973).

The study by Hammar et al. (2008, after Engell-Sørensen and Skyt, 2001) showed that the construction of wind farm foundations in the Öresund area at a suspended solids concentration of 10 mg/l did not significantly affect fish distribution either after 1 day or 1 month (Hammar et al., 2008, after Engell-Sørensen and Skyt, 2001).

The following table summarizes the available data for species found in the Baltic Sea. In general, one can find increased sensitivity of pelagic eggs already from low concentrations of suspension (from 5 mg/l) and increased mortality of larvae in the yolk sac stage (from 10 mg/l). Apart from these cases (not counting extreme concentrations), fish are able to avoid polluted areas.

Table 6. Values of suspended solids concentrations and their effect on different stages of fish found in the Baltic Sea according to available literature

Species	Stadium	Concentration of suspended solids	Effect	Data source
Gadus morhua	roe	5 mg/l	egg drop	Rönnbäck and Westerberg, 1996
Clupea harengus	roe	7,000 mg/l	no	Messieh et al, 1981
Clupea harengus	roe	5-300 mg/l	no	Kiorboe et al, 1981
Clupea harengus	larva	20 mg/l	disruption of food intake	Wildish, 1982
Clupea harengus	larva	2000 mg/l	disruption of food intake	Boehlert and Morgan, 1985
Clupea harengus	larva	3 mg/l	evasion	Westerberg et al., 1996
Clupea harengus	larva	10 mg/l	mortality of larvae in the yolk sac stage	Westerberg et al., 1996
Clupea harengus	larva	540 mg/l	decline in growth rate	Messieh et al., 1981
Clupea harengus	larva	19000 mg/l	100% mortality rate	Messieh et al., 1981
Gadus morhua	larva	10 mg/l	mortality of larvae in the yolk sac stage	Rönnbäck & Westerberg, 1996
Gadus morhua	larva	3 mg/l	avoidance response	Westerberg et al., 1996
Gadus morhua	larva	10 mg/l	mortality of larvae in the yolk sac stage	Westerberg et al., 1996
Clupea harengus	fry	12 mg/l	avoidance response	Messieh et al, 1981

Species	Stadium	Concentration of suspended solids	Effect	Data source
Clupea harengus	adult	10 mg/l	avoidance response	Johnston and Wildish, 1981
Osmerus eperlanus	adult	22 mg/l	avoidance response	Wildish and Power, 1985
Gadus morhua Clupea harengus	adult	6-8 mg/l	avoidance response	Westerberg et al, 1996
Pleuronectes platessa	adult	3000 mg/l	mortality	Newton, 1973

Source: Nermer T., Drgas A., Janusz J., et al. "Monitoring of ichthyofauna of the area of the offshore wind farm Central Baltic III. Final Report with Impact Assessment," Marine Fisheries Institute - National Research Institute, Gdynia, 2015.

In a publication on the classification of the impacts of individual factors associated with the construction, operation and decommissioning of OWFs on the living environment of the Baltic Sea (Bergstrom et al., 2014), the negative impact of an increase in suspended solids concentration on fish was classified as medium. Such an assessment consisted of a moderate impact of this factor in terms of spatial extent, low - in terms of duration of impact and moderate in terms of sensitivity of the receptor, which is fish. A slightly different assessment of the impact of increasing suspended solids concentration on fish is presented in a publication by Wilhelmsson et al. (2010), where the harmfulness of this impact was determined to be low (the spatial scale of the impact was classified as extensive, and the temporal scale as short-term).

7.1.2. Release of pollutants and nutrients from the sludge into the water body

The appearance of negative impacts of toxic chemicals at the stage of OWF construction may have different origins, such as through possible leakage from ships or equipment involved in laying cables (as discussed in the chapter on unplanned impacts) and as a result of harmful substances entering the water along with suspended matter lifted from the bottom as a result of foundation or cable laying work on the seabed.

The most sensitive stages of fish to exposure are maturing females, young embryos, larvae just after yolk sac resorption and early larval stages. A number of studies show that staying with maturing females even in low concentrations of substances that accumulate in tissues can negatively affect their reproductive organs. The effects are usually not seen until the next generation. Common morphological deformities are deformities of the lower jaw, eyes, spinal anomalies and reduced larval size at hatching. The physiological changes that occur as a result of exposure to toxic substances are most often a lowered heart rate and hormonal disturbances (effects on ovulation and spawning). As a result, motor skills like swimming ability and balance disorders deteriorate. Being in a polluted environment can also affect the effectiveness of fish nutrition (Rosenthal et al, 1986; Dethlefsen et al, 1988; von Westernhagen, 1988 after Sindermann, 1994; Struhsaker, 1977; Wedemeyer et al, 1984).

Species in which numerous deformities have been observed due to high concentrations of harmful substances in the North Sea include dab (Limanda limanda) (Dethlefsen et al., 1986), flounder (Dethlefsen et al, 1986), whiting (Dethlefsen et al., 1986), Atlantic cod (Gadus morhua) (Dethlefsen et al., 1986), plaice (Pleuronectes platessa) (Dethlefsen et al., 1986) and herring (Clupea harengus membras) (Linden, 1976).

High concentrations of PCBs in the reproductive organs of North Sea friction fish, such as flounder, herring, rockfish and whiting, can cause high embryonic mortality. The threshold value above which normal development of eggs and larvae is threatened is 0.12 ppm PCBs (von Westernhagen et al, 1981, 1988; Hansen et al, 1985; Westin et al, 1985; Cameron et al, 1986).

The Helsinki Commission (HELCOM) has proposed a list of chemicals whose presence in the sediment should be monitored if dredging is planned in the area. These are mainly heavy metals (cadmium, chromium, copper, lead, mercury, nickel, zinc, arsenic), chlorinated biphenyls, organochlorine and organophosphate pesticides, tributyltin (TBT) and its breakdown products, total petroleum hydrocarbons (TPH), polychlorinated dibenzodioxins (PCDDs), polychlorinated dibenzofurans (PCDFs), PCBs (congeners according to IUPAC 28, 52, 101, 118, 138, 153, 180), sum of PAH9 (anthracene, benzo[a]anthracene, benzo[ghi]perylene, benzo[a]pyrene).

The risk of releasing larger amounts of these substances from sediments during construction activities is low due to the low concentrations found in sediments in the southern Baltic region. Based on available data, it is known that mercury concentrations in the surficial sediment layer in the area of the planned project, and cadmium concentrations at elevated levels (Korpinen and Laamanen, 2010).

In 2010, studies were conducted on the content of polychlorinated biphenyls, organochlorine pesticides and heavy metals (copper, zinc, cadmium, lead, mercury) in sediments from various locations of the Polish Marine Areas, including an area close to the area of the planned project. Based on the results of this work, the region was considered a reference, that is, relatively free of pollution. The results of the study indicate the validity of this assumption, as the aforementioned substances were not found in the sludge in concentrations that could cause a negative biological effect (Dabrowska et al., 2013).

Studies of the concentration of heavy metals (copper, zinc, cadmium, lead, mercury) in the sediments and tissues of flounder*(Platichthys flesus*) from the area under consideration, carried out in 2011, indicate a low level of accumulation of harmful substances in fish tissues (Polak - Juszczak, 2013).

Also, during studies of the content of ∑DDT, HCB, PCDD/F in sediments in the area close to the planned OWF project, the concentrations of these pollutants were not found to have toxic effects on marine organisms (Szlinder-Richert et al., 2012).

Wilhelmsson et al. (2010) assess the risk of significant negative impacts from toxic chemicals as low and occurring within a limited spatial range.

7.1.3. Noise and vibration emissions

Acoustic disturbance is among the most important environmental impacts from offshore wind farm construction activities. Their sources are mainly work on the construction of foundations for the turbines and increased traffic of vessels.

Noise levels associated with foundation construction can reach 260 dB re: 1 $^{\mu Pa2s}$and cable laying work can generate noise as high as 178 dB re: 1 µPa2s (Wilhelmsson et al., 2010).

These values are largely dependent on the type of foundation construction. The highest sound intensity is associated with the construction of truss foundations and monopiles. Significantly less risk is generated in the case of gravity foundation structures, the construction of which does not involve piling (Hammar et al., 2008, after Bergstrom et al., 2014).

Previous studies show that noise can significantly negatively affect the development and life of fish (Popper, Hastings, 2009). Among the effects of anthropogenic sounds are: damage to body tissues (Hastings, Popper, 2005), permanent and temporary loss of hearing capabilities (Smith et al, 2004; Hastings et al, 1996; McCauley et al, 2003), as well as changes in fish behavior (Mitson et al, 2003). It

has also been shown that noise-related environmental stress can induce endocrine and physiological responses in fish (Wysocki et al., 2006; Smith et al., 2004, Santulli, 1999). Ambient sounds can also affect the fish's communication abilities (Amoser et al., 2004), ability to locate prey through acoustic masking (Fay and Simmons, 1999), and their spatial orientation (Lagardère et al., 1994). In addition, human-generated sounds and vibrations can induce fish to leave feeding grounds, hiding places and change spawning territories (Slotte et al., 2004), thus affecting the survival rate of individuals and their reproductive success.

The risk of death or serious injury from noise associated with foundation construction applies to a zone tens to hundreds of meters from the sound source. Some authors (e.g., Caltrans, 2001) emphasize that the high levels of sound pressure generated when piles are driven into the seabed can permanently damage the swim bladder and hearing organs of fish.

A direct effect resulting in death has been observed during piling (bridge construction) within a 50-meter radius of the noise source (Wilhelmsson et al., 2010) while damage to hearing organs or tissues can occur within several hundred meters (Nedwell and Howell, 2003).

In the case of fish, the level of noise that comes from piling work and can cause adverse effects in the form of mortality or damage, the level of which can vary and be reversible or irreversible. In the case of fish that have a swim bladder, it should be recognized that they are more susceptible to acoustic impact, in addition, the use of the swim bladder for hearing processes is of importance. For fish without a swim bladder, the peak noise level that can cause mortality or permanent damage was determined to be 213 dB (219 dB SELcum), and for fish with a swim bladder involved in hearing processes, 207 dB (207 dB SELcum) (Popper, Hawkins et al.,2014). The current data in this area was taken into account when analyzing acoustic impacts and determining minimization measures.

Sublethal impacts mainly boil down to avoidance responses and occur over a much larger radius, usually reaching several thousand meters, from the noise source. Studies by Nedwell and Howell (2003) have shown that when monopal foundations are built, the radius of the avoidance zone is up to 2,000 m for salmonids and up to 10,000 m for cod.

The avoidance response can negatively affect spawning processes in the vicinity of ongoing construction work. This effect is a much greater threat to the population when the avoidance involves an area where environmental conditions are particularly favorable for spawning and there are no areas of similar character nearby. According to Wilhelmsson et al. (2010) sublethal effects of noise impacts can be classified as short-term but having a wide spatial extent. The harmfulness of this factor to local ichthyofauna assemblages was determined to be low. However, these authors emphasize the potential increase in the harmfulness of this factor in relation to cumulative impacts, when the construction of further OWFs or other projects with similar impacts, may cause avoidance of a particular area for a longer period of time (long-term impact).

A report on the assessment of the impact of underwater noise generated by 2 MW wind turbines located in the UK indicates that during piling, fish reaction is possible up to several kilometers away, while permanent damage to fish bodies is possible within a radius of several hundred meters (Nedwell et al., 2003).

Studies in the Baltic prove that cod and herring are capable of picking up sounds emitted during piling from a distance of 80 kilometers, while flounder are capable of picking up sounds from several kilometers away from the sound source (Thomsen et al., 2006). Due to the characteristics of the noise generated and the phenomena of sound propagation, the intensity level presented in the model at a distance of 80 km was higher than the background noise for waves with frequencies from 63 Hz to 2.5 kHz. This range largely overlaps with the auditory capabilities of cod and herring. Measurements made at a distance of 10 km and at closer sites showed that the noise level was higher than the background

noise for the entire spectrum studied (30 Hz - 4 kHz), which includes sounds heard by flounder (Thomsen et al., 2006). The presence of the listed species was noted in the area designated for the planned project.

During the construction phase of the wind farms, there is also a potential threat to fish from increased noise levels generated by increased ship traffic in the area. The type and intensity of the sounds emitted depends mainly on the size of the ships and the propulsion systems used on them (Thomson, 1995).

Noise generated by moving ships and motor boats can also affect the spatial distribution of fish, avoiding acoustic stress (Soria, 1996). Responses involving avoidance of passing vessels have been reported in studies conducted on Baltic populations of cod, herring and sprat, which exhibit the best sound-receiving abilities of the major species exploited by fisheries (Mitson, 1995).

In addition, an *in situ* experimental study conducted in the WWF Natural Miramare Marine Reserve protected area showed a change in the behavior of the red-footed goby (Gobius cruentatus) and chestnut chromis*(Chromis chromis*) in the presence of motor boat sounds (Picciulin et al., 2010). Laboratory studies of these species and the black curlew*(Sciaena umbra*), on the other hand, showed significant negative effects on their communication through acoustic masking effects (Codarin et al., 2009). In contrast, other authors (Wysocki et al., 2006) emphasize that noise can cause physiological responses in fish, such as increased cortisol secretion.

It should be emphasized that the noise generated during the OWF construction work affects not only adult fish, but also their early developmental stages - embryonic (egg), larval and juvenile stages. Significantly, adult fish, thanks to their ability to move considerable distances, often exhibit a response of avoiding harmful sound (Mitson et al., 2003). However, larvae and other early life stages of fish, with significantly less swimming ability, are more vulnerable than adult fish to the negative effects of noise (Wahlberg and Westerberg, 2005). Unfortunately, there is much less knowledge about the effects of noise on eggs, larvae and juvenile marine fish than for adult fish.

Most studies on the effects of sound on early stages of fish are based on the seismic method, which uses air gun devices as the sound source (Piper et al., 1982; Dalen & Knutsen, 1987). It involves creating a strong pulse of low-frequency sound by violently releasing compressed air from a several-liter metal chamber, resulting in a brief shock and vibration of the air bubbles. The sound parameters depend on the volume and pressure of the chamber, which refills, several times a minute (Wille, 2005). Other stimuli used in the experiments are loud pulses of low-frequency sound (Popper, 2009) and mechanical shocks (np. Jensen and Alderice, 1983, 1989; Dweyer et al., 1993).

Placing cod eggs in close proximity to the firing of an *air gun* type device did not significantly affect their survival rate (Dalen and Knutsen, 1987). On the other hand, Kostyuchenko's (1973) results show damage to Black Sea fish eggs at a distance of 20 meters from the sound source, induced by seismic methods. These discrepancies in results may be due to the fact that noise impacts on early life stages of fish depend on a number of factors: species, life stage, distance of the organisms from the sound source, and exposure time. The occurrence of both species differences, as well as differences due to distance from the sound source and developmental stage, was demonstrated by Booman's (1996) *air gun* experiments on three species: herring*(Culpea harengus*), cod (*Gadus morhua*) and plaice*(Pleuronectes platessa*). They made it possible to find a small effect of sound (in the range of 220 to 242 dB re $^{1\mu Pa2}$) on the mortality of yolk sac cod larvae. In the case of yolk sac herring larvae, the impact proved to be insignificant due to the high overall mortality rate. Significant effects on cod larvae at the stage after yolk sac resorption were recorded at noise ≥223 dB. A similar effect was noted for cod at the juvenile stage at 242 dB, while for herring and plaice at the same stage of development, a small, non-significant effect appeared above 242 dB. The observed effect was dependent on the distance from the source of the sound; significant mortality of cod and herring was recorded as early as 5 m, although the greatest effect of the sound occurred at a distance of 1.4 m from the source.

Experiments on the effects of sound on common sole larvae (Solea solea) used frequencies from 50 to 1000Hz with sound levels ranging from 0 to 210db re $^{1\mu Pa2}$, with a single signal measuring up to 186 dB re $^{1\mu Pa2s}$(Bolle, 2012). The results of these experiments showed that there were no statistically significant differences in mortality of larvae treated with sound compared to the control group (Bolle, 2012).

The information presented above proves that even if the impact of noise on eggs and larvae is significant, sometimes even fatal, it is a local impact occurring at a short distance from the source of the sound - on the order of a few, several meters. Of course, it cannot be ruled out that noise with a source even much farther away, although it does not cause increased mortality, can affect the reduced growth rate of larvae. However, there is a lack of literature information on the subject.

In a paper summarizing the state of knowledge on the environmental impact of OWF construction and operation, Wilhelmsson et al. (2010) estimate that the risk of death or serious injury from construction-generated noise occurs only to the local extent and, given the potential for fish escape and the use of mitigation measures, is low.

In contrast, the sublethal effects of noise exposure (primarily related to the avoidance response discussed earlier) can, according to Wilhelmsson et al. (2010) classify as short-term, but with a broad spatial scope. The harmfulness of this factor to local ichthyofauna assemblages was determined to be low. However, these authors emphasize the potential increase in the harmfulness of this factor in relation to cumulative impacts, when the construction of further OWFs or other projects with similar impacts, may cause avoidance of a particular area for a longer period of time (long-term impact).

Bergstrom et al. (2014) assess the potential impact of noise on fish in the Baltic proper as moderate. This assessment consists of a medium to high spatial extent of the impact with its short-lived nature and low to medium sensitivity of the receptor (ichthyofauna).

7.1.4. The formation of a mechanical barrier

Migration routes of spawning and feeding fish species of economic importance, including cod, herring and salmon (Netzel and Janusz, 2005 in Zaucha et al., 2009), run through the site of the planned projects. Work on the construction of the OWF involves, among other things, an increase in the intensity of ship traffic in the area as well as the emergence of underwater structures. Such an accumulation of large-scale objects can create an underwater physical barrier to fish migration during the construction period. However, this is a relatively short-lived stage, and fish have the ability to actively move to avoid these barriers. Danish studies have shown that the existence of the OWF has no negative impact on fish migration routes (Leonhard et al., 2011).

7.1.5. Habitat changes

Habitat changes caused by the construction of the wind farm may affect ichthyofauna through changes in the morphology of the bottom and the nature of the sediment that may directly affect the living and reproductive conditions of ichthyofauna, and indirectly, through the impact of habitat changes on benthic organisms that are the food source of fish.

Changing sediment structure can, among other things, negatively affect the reproductive success of fish (ICES, 1992; ICES, 2001; Phau et al, 2004; Posford Duvivier Envirnment and Hill, 2001; Birklund and Wijsman, 2005). This is particularly important for herring, which prefer specific habitats characterized by shallow depths and suitable substrate that provides for egg attachment (Kiorboe et al., 1981; Posford Duvivier Environment and Hill, 2001). Numerous studies have shown that changes in the structure of sediments that serve as spawning grounds result in a lack of spawning or create unfavorable conditions for egg and fry development (de Groot, 1979; Phua et al., 2004). Changes in sediment structure and chemicals released from the sediment (Spanggaard, 2006) also affect benthic biocoenoses

(phytobenthos, plants, invertebrates), which can be removed or destroyed. This can result in a deterioration of the food base for benthic fish, for which benthic organisms are an important food base (Daan et al, 1990; Cohen et al, 1980; Sissenwine et al, 1984; Jones, 1984 for: ICES, 2001).

It should be pointed out that the works carried out will cause the suspension of fine sediment fractions in the water depths, which will then fall to the bottom covering them with a layer of fine sediment.

The results of sediment dispersion and sedimentation modeling showed that the extent of this process will cover the entire area of the planned project, and the maximum thickness of the additional sediment layer will not exceed 3.5 mm (Report 2015). However, such a relatively small change in habitat can disrupt the development of benthic eggs (herring, bottomfish, gobies) by covering already deposited grains or hindering their deposition on the altered sediments. In the case of the former, such an impact has been confirmed by literature data (Report 2015).

Habitat change during construction will lead to the complete destruction of the benthos in the areas of excavation for foundations and trenches where cables will be run. This will deplete food resources for benthic fish. However, the area where the habitat change will completely eliminate benthic organisms will be relatively small. Given the active movement of fish in search of food, such a loss of organisms included in the diet of bentophagous fish can be considered insignificant.

Also, the reduction in the food base of fish caused by the negative impact of covering the bottom with a layer of fine sediment settling from the water depths should not be significant.

The results of the zoobenthic structure and its susceptibility analyses presented in Appendix E of the Report and in Section 2 of Volume IV of the Report indicate that the only benthic species significantly exposed for this reason, which at the same time constitutes a relatively important component of the diet of fish (mainly flounder), is the bivalve Cerastoderma glaucum (heartfish). However, its contribution to the zoobenthic biomass of the area in question is very small (<7% of the total zoobenthic biomass). The effect of covering the bottom with an additional layer of sediment on the benthos is considered negligible. Therefore, there is no reason to assume that the associated reduction in the food base of benthic fish can negatively affect ichthyofauna during construction activities.

Given that even in the most far-reaching scenario the significance of this impact on fish is negligible or small, minimization measures are not required.

Habitat alteration due to seabed work during construction is a direct, negative impact on fish (especially benthivores and bottom spawners) of local extent, short-term, reversible, repeatable during the construction period, of medium intensity.

The results of the impact assessment in terms of the increase in suspended solids in water, caused by the implementation of the Project in the variant constituting the NIS 2015, for fish species such as goby, demersal, cod, plaice, turbot, flounder, sprat and herring show insignificant impacts of local and short-term nature with low intensity. The assumed parameters of the currently anticipated Project are 70% less than the 2015 NIS, which means that the nature and magnitude of these impacts will be less than those identified for both the variant assessed as the 2015 NIS, as well as those identified in the Environmental Decision.

7.1.6. Summary

Table 7. Potential impacts of OWF on fish - construction phase

Type of emission or disturbance	Rationale for selection and key parameters and factors affecting the level of impact
Increase in the concentration of suspended solids in water	As a direct result of disturbing the structure of bottom sediments during construction activities, suspended solids will rise and spread in the water depths. The most important parameters affecting the level of impact are: • the type, dimensions and number of foundations to be built and the length of cables to be laid; • a type of rock material that forms the seabed.
Release of pollutants and nutrients from the sludge into the water body	Violation of the structure of bottom sediments will result in the passage of pollutants and nutrients contained in them. These substances can negatively affect ichthyofauna. The most important parameters affecting the level of impact are: • the type and amount of toxic chemicals released; • weather conditions; • a type of rock material that forms the seabed.
Noise and vibration emissions	Fish will be exposed to underwater noise and vibration emissions during the installation of monopal, jacket and tripod foundations. The most important parameters affecting the level of impact are: • number of foundations; • diameter of the pile(s); • power of the jackhammer; • piling time. Explosions of unexploded conventional weapons deposited on the seabed (unplanned activity) can also be a source of noise.
The formation of a mechanical barrier	Foundation structures gradually appearing during the construction phase may provide an underwater physical barrier to fish migration during the construction period. The most important parameters affecting the level of impact are the number, diameter and spacing of foundations.
Habitat changes	Habitat changes caused by the construction of the wind farm, in particular the change in bottom morphology, sediment substrate composition and structure, may directly affect the living and reproductive conditions of ichthyofauna and indirectly, through the impact of habitat changes on benthic organisms that are the food source of fish. The most important parameters affecting the level of impact are: • the type, dimensions and number of foundations to be built and the length of cables to be laid; • a type of rock material that forms the seabed.

Type of emission or disturbance	Rationale for selection and key parameters and factors affecting the level of impact
Oil spill	At each stage of the project, vessels (ships, barges, etc.) will be used, from which small spills of petroleum substances (lubricating and diesel oils, gasoline, etc.) into the water depths may occur during normal operation. Pollution entering the water's depths during normal ship operations is the second largest source of oil pollution at sea. From this source, about 33% of the oil entering the environment enters the waterways (mainly due to increased ship traffic in the Baltic Sea region (Kaptur, 1999). In comparison, about 37% of the oil that enters the sea comes from river runoff from land, and only in third place are tanker disasters (12%). Release of petroleum substances can also occur in emergency situations (ship failure or collision, power substation failure, construction disaster). Heavier oil fractions can be sorbed on the surface of organic and mineral suspensions, which will cause their specific gravity to increase and gradually sink to the bottom. Pollution of water and bottom sediments can negatively affect ichthyofauna. The most important parameters affecting the level of impact are: • the type and amount of oil substances released; • weather conditions; • a type of rock material that forms the seabed.
Contamination of water depths and bottom sediments with antifouling agents	At each stage of the project, vessels (ships, barges, etc.) will be used, from whose hulls some amounts of antifouling substances may be released into the water depths during normal operation. Pollution of water and bottom sediments can negatively affect ichthyofauna. The most important parameters affecting the level of impact are: • the type and amount of antifouling substances released; • a type of rock material that forms the seabed.
Accidental release of municipal waste or domestic sewage	At each stage of the project, on the vessels as well as at the construction facilities located on land (at the port serving the implementation of the project), waste will be generated, mainly municipal and other waste not directly related to the construction process, as well as domestic sewage. Waste and wastewater can be accidentally released into the sea when picked up from ships by another vessel and in the event of an accident. Pollution of water and bottom sediments can negatively affect ichthyofauna. The most important parameters affecting the level of impact are: • the type and amount of waste or wastewater released;

Type of emission or disturbance	Rationale for selection and key parameters and factors affecting the level of impact
	• weather conditions; • a type of rock material that forms the seabed.
Accidental release of chemicals and waste from farm construction	During the construction of the wind farm, waste directly related to the construction process will be generated on vessels, at construction facilities located onshore (at the port serving the project) and at the project site. These can include damaged parts of the farm's assembled components, cement, grout, mortar, binders used to join the foundation and power plant components, and other chemicals used during construction work. They can be accidentally released into the sea. Pollution of water and bottom sediments can negatively affect ichthyofauna. The most important parameters affecting the level of impact are: • the type and amount of waste or wastewater released; • weather conditions; • a type of rock material that forms the seabed.

7.2. Operation stage

7.2.1. Emissions of compounds from corrosion protection agents

During the operation of the farm, contamination of the water table and bottom sediments with compounds from corrosion protection agents for steel foundation structures may occur.

The most common anti-corrosion method used in the marine environment is cathodic protection. It can be implemented as galvanic or electrolytic protection. Galvanic cathodic protection involves installing aluminum or zinc anodes on the foundations. Anodes are gradually consumed and Al or Zn passes into the water depths and accumulates in bottom sediments.

In electrolytic cathodic protection, the protected object becomes the cathode of an electrolytic cell supplied with DC current from an external source. The anode used in this circuit is mostly insoluble. Among the most durable anode materials used in this method are platinum and titanium electrodes coated with a 2-3 µm layer of platinum. With electrolytic cathodic protection, no impact on water quality or sediment is observed.

While aluminum (Al) is widely distributed and found in the biosphere, its toxic effects have mainly been observed in sudden acidification of inland water environments (Poleo, 1997). Zinc (Zn), on the other hand, is an essential element in most organisms, but in high concentrations it poses a threat to the health of living organisms, including fish (Eisler, 1998; Amundsen et al., 1997). The bioavailability and toxicity of zinc in aquatic organisms has been shown to depend on the concentration of the metal in water (Chen et al., 2000; Rashed, 2001). Current studies of zinc concentrations in fish do not show that the standard (see table below), which is 50 $^{mg/kg^{-1}}$, is exceeded.

Table 8. Content of individual elements in tissues of fish from the Baltic Sea

Genre		N	Cu [mg $^{kg-1}$]	Zn [mg $^{kg-1}$]	Cd [µg $^{kg-1}$]	Pb [µg $^{kg-1}$]

With regard to aluminum, it should be pointed out that it is an element that is widely distributed on Earth. It is found in soil, water and air. It is found in all natural waters, where it can occur in soluble and insoluble forms in inorganic as well as organic compounds. Aluminum compounds in the aquatic environment show varying degrees of toxicity, which depends on the reaction of the water. The pH range of 5.1-5.5 is dominated by monomeric toxic hydroxocomplexes $Al(OH)^{2+}$, $Al(OH)^{2+}$, which pose a threat to aquatic organisms: phytoplankton, crayfish, snails and fish. The effect of toxic forms of aluminum is to penetrate organisms, accumulate and disrupt the osmoregulatory balance of fish. With an increase in pH above 6 and a high concentration of aluminum, the die-off effect is due to clogging of the fish's gills (Widlak, 2011 for: Playe, Wood, 1990; Bezak-Mazur, 2004; Herbs et al. 2008). Both high and low concentrations of aluminum are a factor in fish felling.

Due to the natural conditions of seawater (pH=8.1), the predominant form of aluminum is the hydroxide hydroxocomplexes $Al(OH)_4$, $Al(OH)^{30}$, but it can also bind to fluorine, fossilized organic matter or be organically chelated.

Based on analyses of the inhibitory or phective concentrations of aluminum causing 10% inhibition of growth or physiological process (IC10 or EC10) and the no effect concentrations determined for 11 marine species from different toxicity levels (including temperate and tropical species), a guideline for aluminum content in marine waters of 24 µg total Al/l was developed (Golding et al.) It has been shown that aluminum in dissolved and/or particulate form can contribute to the occurrence of chronic (chronic) toxicity depending on the species studied. Among the most sensitive of the species analyzed are: *ceratoneis closterium* diatom, *Mytilus edulis clam* and *Saccostrea echtinata* oyster. Toxicity to these species was due to the presence of soluble forms of aluminum ($Al(_{OH4}$) and aluminum hydroxide ($Al.(OH)^{300}$; however, both dissolved and particulate forms of aluminum contributed to toxicity to the diatom and green alga *Dunaliella teriolecta*. In contrast, aluminum toxicity to the green algae

Tetraselmis sp. was caused exclusively by aluminum in molecular form. Four species, the brown macroalga Hormosira banksi, the sea urchin embryo *Heliocidaris tuberculata*, and the juvenile individuals of two fish species Lates calacalifer and Acanthochromis polyacanthus, were not adversely affected at the highest concentration used.

Regarding the impact of corrosion protection systems, the effects of Al emissions from galvanic anodes have been analyzed in several studies, mainly in port environments or laboratory experiments (Kirchgeorg et al., 2018). Gabelle et al. (2012) showed a significant increase in Al concentrations in sediments near the anodes in the harbor basin (Le Havere), while Al concentrations in the water did not increase due to dilution. Experiments with tanks filled with sediment-free seawater conducted by Deborde et al. (2015) showed high concentrations in embedded and suspended particulate matter. They assumed that this enrichment of Al suspended matter could be of importance to the filtrators. Deborde et al. (2015) also suspected that the dissolved fraction in seawater is irrelevant in the environmental conditions of these waters due to the dilution effect. Mao et al. (2011) investigated Al accumulation in the mussel Mytilus edulis in a harbor environment and showed that the digestive glands are short- and medium-term sites of Al accumulation.

Caplat et al. (2010) investigated dissolved Al and Zn from galvanic anodes and the corresponding sulfate salts using sea urchin bioassays. And they indicate a lower influence of Al and Zn coming from galvanic anodes (Kirchgeorg et. al., 2018).

The effect of dissolved and precipitated Al on various diatoms was studied by Gillmore' et al. (2016). They showed that toxicity can be caused by dissolved or precipitated Al depending on the diatom species. These studies also show that Al concentrations causing chronic toxicity in different species of marine diatoms vary significantly.

7.2.2. Noise and vibration emissions

Among the changes in long-term habitats associated with OWFs is the change in the acoustic environment, caused by noise and vibration from turbine operations, among other things (Spanggaard, 2006). The level of noise intensity generated by these devices depends on the type of turbine, wind speed, the number of power plants in operation and their mutual distances as well as local hydrological, geological and depth conditions. The frequency of sound generated in the water by an operating turbine ranges from 1-400 Hz and the level from 80-100 dB $^{1\mu Pa2s}$and increases with the number of turbines (Nedwell and Howell, 2003). Due to the low frequency and intensity of the noise, there is no risk of permanent damage to hearing organs or fish tissues from the noise generated by operating wind turbines (Wahlberg and Westerberg, 2005).

On the other hand, the avoidance effect of regions in the immediate vicinity of the turbine is likely, but the extent of this impact should not exceed a few meters. The avoidance response to the increased pressure associated with the generated sound occurs in a zone up to 4 m from the turbine (Wahlberg and Westerberg, 2005). The effect associated with the response to particle acceleration caused by turbine operation has an even smaller range of up to 1 meter. No detection of this anomaly by cod, flatfish or salmonids was found within 10 meters of the turbine (Sigray et al., 2009 after Wilhelmsson et al., 2010).

On the other hand, experimental studies conducted in aquaria (Muller, 2007 after Wilhelmsson et al., 2010) have shown the response of plaice and cod to noise generated by turbines. However, it was not strong enough to result in the permanent abandonment of the habitat.

According to a report on the impact of turbine noise in the area of the Vindeby offshore wind farm (Engell-Sorensen, 2002), a response of avoidance by flat fish of areas directly approaching (up to several meters from the foundation) to the turbines can be expected with little probability.

Other studies show that the possible negative stimuli generated by noise and vibration emitted in the immediate vicinity of the turbine are not significant enough to prevent fish from accumulating near the turbine foundations covered with encrusting organisms (the "artificial reef" effect). Acoustic cruises in the Horns Rev offshore wind farm area showed that most, and mainly large fish, were located directly around the turbine foundations (Elsam Engineering A/S, 2005).

At the same time, during the operation phase of the offshore wind farm in the described area, there may be a slight reduction in noise from shipping and fishing due to restrictions on vessel traffic and a possible ban on fishing in the area of the OWF. However, it is difficult to determine to what extent it will be offset by increased traffic of service units.

Noise impacts at the operational stage can be made according to Wilhelmsson et al. (2010) classify as long-lasting but with very limited spatial coverage. The harmfulness of this factor to local ichthyofauna assemblages was determined to be low.

Bergstrom et al. (2014) assess the potential impact of mining noise on fish in the Baltic proper as moderate. This assessment consists of the medium spatial extent of the impact with its long-term nature and low sensitivity of the receptor (ichthyofauna).

At the operation stage, there may also be noise emissions from operating vessels, which may appear at the OWF site in connection with maintenance work. Responses involving avoidance of passing vessels have been reported in studies conducted on Baltic populations of cod, herring and sprat, which exhibit the best sound-receiving abilities of the major species exploited by fisheries (Mitson 1995). The response of fish to noise also depends on their physiological state. Herring, which have very good hearing, are observed to avoid sound sources associated with ship traffic and fishing gear usually outside the spawning season (Olsen et al. 1983; Vabo et al., 2002), and this behavior changes when herring spawn (Nøttestad et al. 1996; Axelsen et al. 2000).

On the other hand, the avoidance effect of regions in the immediate vicinity of the turbine is likely, but the extent of this impact should not exceed a few meters. The avoidance response to the increased pressure associated with the generated sound occurs in a zone up to 4 meters from the turbine (Wahlberg and Westerberg, 2005). The effect associated with the response to the acceleration of particles caused by the operation of turbines has an even smaller range, reaching a distance of 1 meter.

7.2.3. The formation of a mechanical barrier

The presence of wind turbine structures may to a small extent constitute an underwater physical barrier to fish migration. However, far more important are the positive consequences of the IMF's existence in the form of the creation of a new "artificial reef" habitat (allowing shelter, potential breeding and foraging sites). Danish studies have shown that the existence of the OWF has no negative impact on fish migration routes (Leonhard et al., 2011).

7.2.4. The creation of an "artificial reef"

The appearance of new elements in the environment, such as structural elements of turbines, mainly their foundations and erosion control structures, is associated with the creation of a new habitat characterized by hard ground. The term "artificial reef" is used to refer to these types of structures (wind turbines, drilling towers, or artificial structures placed in the environment to create hard ground).

Time of colonization

The process of colonization of artificial reefs often begins immediately (a few hours or days) after the structure in question is installed (Norsker, 1997). The presence of invertebrates and fish was observed on artificial reefs shortly after their creation (Stone, 1978; Grove et al, 1983; Bohnsack and Sutherland,

1985; Ambrowe and Swarbrick, 1989). Often, fish populations become very abundant at such sites within a few months (Turner, 1969; Stone et al., 1979; Bohnsack and Tolbot, 1980). However, it usually takes 1-5 years for a stable artificial reef system to develop (Bohnsack and Sutherland, 1985). Hard substrate (also in the form of IMF structures) is characterized by a rapid rate of colonization by epiphytic organisms, macrophytes, invertebrates (Newell et al., 1998; Feger, 1971). Such a phenomenon has been observed, for example, in the case of the Nordsee research platform (Garcia, 1991) or the IMF Horns Rev (Leonard, 2000). Studies show that colonization of wind farm structures by epifauna occurs as early as 5 months after commissioning (Leonhard, 2000).

After the construction phase is completed, representatives of numerous fish species return to their previous habitats. There are also emerging opportunities to settle new habitats. In the area of artificial reefs, fish populations similar to those observed in the wild have been reported (Relini et al., 1994), although there may also be an increase in biodiversity.

Causes of colonization and increase in density

Usually, the appearance of new structures that provide hard substrate results in an increase in the abundance of certain fish species. This is a result of the creation of a new habitat, providing shelter for ichthyofauna, as well as an increase in food resources as a result of the emergence of encrusting organisms. An increase in the abundance of certain ichthyofauna taxa may be an additional factor in attracting predatory fish. Some authors have also argued that structural elements attract fish by providing them with points to help them orient themselves in space (e.g. Bohnsack and Sutherland, 1985; Bohnsack, 1989).

Underwater observations in the offshore areas of wind farms in the North Sea have shown that wind farm foundations, which consist of, among other things, stones and boulders with many holes and crevices, provide an attractive hiding place for cod aged 2-3 years (Reubens et al., 2011). Atlantic cod find refuge here from ocean currents and pressure from both predators (Bohnsack and Sutherland, 1985; Wilhelmsson et al., 2006) and fisheries. Thus, offshore wind farm areas in the North Sea are seen as an opportunity to enhance the health of Atlantic cod populations (Reubens, 2014). A similar ecologically important function as a habitat for fish has been attributed to the establishment of oil rigs in the Southern California area (Helvey, 2002).

The creation of new habitats may result in spawning conditions for herring*(Clupea harengus*), foxfish*(Agonus cataphractus*), beluga*(Belone bel*one), cleavers (*Cyclopterus lumpus*), horse mackerel (*Pholis gunnellus*) in the IMF area under consideration (Zocco et al., 2006). Structures of wind turbine structures can be both places of refuge and places of reproduction or development of the early stages of many fish species. A pelagic species - herring*(Clupea harengus*), which is found in the OWF area, spawns near the bottom. The presence of stable substrate in the form of OWF structures will create favorable spawning conditions for this species (Spanggaard, 2006).

Representatives of gobies (Pomatoschistus spp) are demersal spawning fish that spawn on hard substrates (such as clam shells). The colonization of OWF structures by sedentary organisms (such as clams) can therefore create conditions favorable for the reproduction of this group of fish (Spanggaard, 2006). Also, the study by Wilhelmsson et al. (2006) confirm the increased abundance of goby fish in the immediate vicinity of the turbines. The appearance of macrophytes overgrowing the hard substrate created by OWF structural elements can create a favorable environment for the reproduction and development of the early stages of many ichthyofauna taxa (Gregg, 1995; Nelson, 1985; Norsker, 1997). Algae may also be preferred as refuge sites for juvenile stages (Spanier et al., 1990; Ambrowe and Swarbrick, 1989). The presence of algae can also increase food availability for many species (Hueckel and Buckley, 1987).

If restrictions are placed on fishing in the offshore wind farm area and the area is excluded from shipping (or restrictions are placed on these activities), pressure from both these sectors will decrease and the

farm area can provide a refuge for fish, both adults and their early life stages - larvae and fry - these areas can be considered protected areas (Degraer and Brabant, 2009). The eventual cessation of fishing in the area may result in a rapid increase in biomass, incidence as well as larger sizes of representatives of fish species that were previously exploited. An increase in species richness is also likely (Halpern, 2003). Evaluation of the positive effect depends on the size of the area, if any, excluded from fishing, the number of artificial reefs in the area, and how long it has been since fishing in the area stopped (Roberts et al., 2001).

Although the amount of productivity growth of individual regions will largely depend on the specific conditions in the area (Bohnsack, 1989), the direction of the predicted changes (i.e., productivity growth rather than decline) is clearly positive.

However, it should be remembered that the increase in abundance, and in some cases diversity of ichthyofauna, in the area of artificial reefs is not necessarily due to increased production in these areas. It can only be the effect of "attracting" fish from nearby areas by creating more favorable conditions for feeding or avoiding predator pressure. The debate over this issue has remained an important part of research on the impact of artificial reefs on fish stocks and fisheries efficiency for years (Pickering and Witmarsh, 1997).

When the cessation of fishing results in an increase in the abundance/productivity of ichthyofauna in an area, there may be migration of fish from these areas to adjacent areas. In some cases, this leads to an increase in the fishing productivity of water bodies adjacent to areas closed to fishing (Murawski et al., 2000).

It is worth mentioning, however, that not all studies carried out in OWF areas unequivocally point to their role as a factor in increasing the abundance and diversity of ichthyofauna in these areas.

Hydroacoustic surveys conducted in the Nysted (Baltic) and Horns Reef (North Sea) offshore areas did not show a statistically significant impact of new habitat elements on fish distribution at both local and regional scales. In the case of the Nysted farm, this may have been due to the very homogeneous taxonomic structure of the benthic fauna that populated the turbine components. The newly formed hard substrate was completely dominated by mussels (M. edulis), which are not an important food component of ichthyofauna in the area, hence no fish were observed to congregate near the turbines. On the other hand, the lack of change in fish distribution and abundance due to the construction of the Horns Reef farm is explained by the authors of the study as a result of the time that elapsed between the construction of the OWF and the time of the study, which was too short and insufficient to form new biocoenoses (Hvidt et al., 2004; Hvidt et al., 2005a; Hvidt et al., 2005b).

The effect of the IMF as a structure that creates an artificial reef can, according to Wilhelmsson et al. (2010) classify it as a positive impact of long-term nature and local scope and its level should be assessed as medium. The elimination of fishing pressure in the area of the OWF was assessed by these authors as a largely positive factor on ichthyofauna having a long-term and broad spatial impact.

Bergstrom et al. (2014) assess the potential impact of new habitat creation on fish in the Baltic as moderate. This assessment consists of the medium spatial extent of the impact with its long-term nature and the medium sensitivity of the receptor (ichthyofauna).

7.2.5. Emission of electromagnetic fields and radiation

During the operational phase of the wind farm, electromagnetic interactions observed around cables transmitting electricity could be a potential threat to fish. The effects of electromagnetic fields on ichthyofauna remain poorly documented to date (Gill, 2001; Gill, 2005; Öhman et al., 2007). Effects of electric and magnetic fields have been observed on some fish species considered sensitive ("electro-sensitive fish") (Rodmell and Johnson, 2005; Gill and Taylor, 2001; Westerberg, 2000). Also, it is known

from experience with fishing done using electricity in freshwater that many fish species (both adults and eggs and larvae) are sensitive to electric fields. This applies to adults as well as larvae and eggs (Fricke, 2000).

The threshold of fish sensitivity to the presence of electromagnetic fields is not well understood. During an experiment on the field-sensitive dogfish shark (Cyliorhinus caniculus), electromagnetic field avoidance of $^{10uV/cm2}$ was observed (Rodmell and Johnson, 2005), which is the maximum expected field strength when using an unburied 150kV/600A 3-core power cable (Gill and Taylor, 2001).

According to the Danish Offshore Wind-Key Environment Issue Report (2006), it is possible to change the behavior of fish subjected to electromagnetic forces around cables by avoiding the zone of influence or attracting fish toward them, depending on the species. In the case of flounder, a significant correlation was observed between these phenomena and electromagnetic field strength. Behavioral changes in fish have been observed in the form of electromagnetic field avoidance (Rodmell and Johnson, 2005) and changes in swimming direction (Westerberg, 2000).

Species of the herring family (Clupeidae) and flat fish (Pleuronectidae) may be exposed to electric fields in the Baltic Sea (Fricke, 2000). Of the species found in the study area, the plaice*(Pleuronectes platessa*) is an example of a species that uses Earth's magnetic interactions and those generated by seawater movement for orientation/navigation (Metcalfe, 1993). The results of an experiment testing the long-term (7 weeks) effects of a static magnetic field (3.7 mT) on juvenile flounder*(Platichthys flesus*) showed no differences in fish survival compared to a control sample (Bochert and Zettler, 2004).

Observations of the sensitivity of hatchlings of sea*trout (Salmo trutta*) larvae to magnetic fields allowed us to conclude that at this stage of ontogenesis, the larvae use exteroreceptors that receive magnetic stimuli from the environment. Such ability gives them the ability to orient themselves in the water's depths and move in a certain direction (Formicki et al., 2004; Sadowski et al., 2003).

The potential impact of the additional magnetic field may also occur in herring*(Culpea harengus*) and sprat*(Sprattus sprattus*) (Fricke, 2000).

It is believed that the electromagnetic field observed around the connection cables may also affect the migratory abilities of the fish. Species that use geomagnetic forces for spatial orientation, such as the European eel (Öhman et al., 2007) or salmonids, are particularly vulnerable to this impact (in the work of Yano, 1997, a reduction in swimming speed was observed in keta individuals subjected to electromagnetic forces). However, other studies have found no significant effect of the presence of high-voltage cables on the migration of silver eel*(Anguilla anguilla*) (Westerberg and Begout-Anras, 1999). Observations involving tracking eel migration routes showed that electromagnetic fields generated by cables associated with the operation of the OWF caused only minor (up to 50 minutes) delays in migration or insignificant changes in the route, without causing interference that could significantly affect migration efficiency (Westerberg et al., 2007 after Wilhelmsson et al., 2010). Similarly, studies conducted on the impact of the power cable connecting Poland and Sweden (SwePol Link) did not show a significant effect of this factor on salmonids (Westerberg et al., 2007 after Wilhelmsson et al., 2010). Also, studies conducted in 1999-2002 by the Maritime Institute of Fisheries on the impact of the construction and operation of this undersea power transmission system between Poland and Sweden (SwePol Link) on the marine environment did not reveal disturbances in the movement of flatfish and juvenile cod. This could be due to the small range of the field's influence: its changes were significant only at a short distance from the cable (up to a dozen meters), while at a distance of several tens of meters from the cable, the changes were within the range of natural changes (Andrulewicz et al., 2003).

In addition to studying the effects of transmission line laying on macroscopic organisms, the scale of disturbance of the earth's magnetic field by current flowing in cables has been studied (Andrulewicz et al., 2003). Changes in the magnetic field were significant only at a short distance from the cable (up to

a dozen meters), while at a distance of several tens of meters from the cable, the changes were within the range of natural variations. During measurements on the seabed above the cable line, no disturbance of flatfish and juvenile cod was observed.

The concentration of cod in the vicinity of the magnetic field, which was observed in the Nysted offshore wind farm area in 2003, is related to the concentration of food in the area rather than to the fish's preference for electromagnetic field locations (Bio/consult as, 2006).

The impact of electromagnetic field changes caused by the construction of the OWF on ichthyofauna can, according to Wilhelmsson et al. (2010) classify it as a small one with a long-term nature and local scope. However, these authors point out the uncertainty of this assessment due to limited knowledge of the impact of this factor on fish, especially with regard to possible disruptions in fish migrations (the barrier effect created by the OWF) and changes in the foraging behavior of cartilaginous fish as a result of long-term impacts.

7.2.6. Summary

A summary of the potential impacts of the OWF operation stage on ichthyofauna is provided in the table below. The table also includes a description of potential unplanned impacts.

Table 9. Potential impacts of OWF on fish - operation stage

Type of emission or disturbance	Rationale for selection and key parameters and factors affecting the level of impact
Emissions of compounds from corrosion protection agents	The impacts of toxic substances during the operation stage are related to the protection of steel foundation structures from corrosion. The most common anti-corrosion method used in the marine environment is cathodic protection. It can be implemented as galvanic or electrolytic protection. With cathodic protection, there will be a gradual release of Al or Zn into the water table. The most important parameters affecting the level of impact are: • the type and amount of substances released, • water quality in the project area, • a type of rock material that forms the seabed.
Noise and vibration emissions	At the stage of operation of the OWF, there are noise and vibrations caused by the operation of the turbines, as well as, to a small extent, the movement of service vessels. At the same time, in the described area, there may be a slight reduction in noise from shipping and fishing due to restrictions on vessel traffic and the possible prohibition or restriction of fishing in the area of the OWF. The most important parameters affecting the level of impact are the number and spacing of power plants.
The formation of a mechanical barrier	The foundations of wind turbines and supporting infrastructure can create an underwater physical barrier to fish migration during the operational period. The most important parameters affecting the level of impact are the number, diameter and spacing of foundations.

Type of emission or disturbance	Rationale for selection and key parameters and factors affecting the level of impact
Habitat changes - the emergence of "artificial reef"	Habitat changes brought about by the creation of an "artificial reef" can have a positive impact on ichthyofauna, thanks to the creation of new hiding places, an increase in the food base, the creation of favorable conditions for the spawning of some species and the development of juvenile forms. The most important parameters affecting the level of impact are the shape, base diameter and number of foundations.
Emission of electromagnetic fields and radiation	Electricity transmission cables transmit an electromagnetic field that can have a slight effect on some fish species. The most important parameters affecting the scale of the impact are the length and type of power cable.
Oil spill	See description for construction phase
Accidental release of municipal waste or domestic sewage	See description for construction phase
Accidental release of chemicals and waste from farm operations	During the operation of the wind farm, waste directly related to the operation of the wind farm will be generated on the vessels, at the facilities located onshore (at the port servicing the project) and at the project site. These may include damaged parts of farm components, cement, grout, mortar, operating fluids and other chemicals used or replaced during maintenance work. They can be accidentally released into the sea. The most important parameters affecting the level of impact are: • the type and amount of waste or wastewater released, • weather conditions, • a type of rock material that forms the seabed.
Contamination of water depths and bottom sediments with antifouling agents	See description for construction phase

7.3. Decommissioning stage

The lifespan of the OWF infrastructure is assumed to be about 25 years (Wilhelmsson et al., 2010). After this period, three options are possible: decommissioning the structures that make up the OWF, leaving the turbine structures stripped of their moving parts (along with the consequences of their continued existence, i.e., the presence of disturbances caused by their presence, but also the preservation of the habitats created on their elements), and continued operation requiring continued maintenance of the efficiency and modernization of the infrastructure (Wilhelmsson et al., 2010). However, in the current state of the law, the latter is unacceptable, as wind farm structures should be properly dismantled ensuring the safety of navigation, fishing or other future uses of the area. The need to decommission offshore wind farms at the end of their operation stems from, among other things, the UNCLOS (1982) international maritime law. Guidelines and standards for how to carry it out are also included in the Helsinki Convention (HELCOM) and recommendations, such as IMO Guidelines and Standards for the

Removal of Offshore Installations and Structures on the Continental Shelf in the Exclusive Economic Zone (1989). According to international maritime law (UNCLOS, 1982), information on the location of structural elements that have not been fully removed must be made public. This may include parts of turbine foundations below the bottom level, erosion protection and power cables.

During demolition, methods and technologies should be used to minimize harmful effects on the environment.

Analysis of this impact is hampered by the lack of experience in this type of project due to the early stage of offshore wind development, as well as the inability to predict what technologies will be available twenty or more years down the road when the dismantling of the farms is carried out (OSPAR, 2008). It is assumed that the primary factors likely to adversely affect the environment will be, as in the case of the construction phase, an increase in the concentration of suspended solids, noise, the threat of contamination by toxic substances, and habitat alteration. The environmental impact of the aforementioned factors is largely dependent on the demolition and removal technology used and the turbine foundation solutions adopted during construction.

7.3.1. Increase in the concentration of suspended solids in water

During the decommissioning phase, operations to remove turbines, foundations and cables may increase the amount of suspended solids in the water table. Liquidation of monopile and jacket-type foundations involves partial removal of piles from the bottom. This will disturb the sediment and increase the concentration of suspended solids in the water tone. Removal of ballast from gravity foundations can also cause a temporary increase in suspended solids in the water table. A temporary increase in the amount of suspended solids in the water tone can also occur when cables are removed from the bottom.

Thus, it can be assumed that there are similar potential risks associated with an increase in suspended solids concentration to those occurring during the construction phase, such as negative effects on larval and egg development, impediments to food acquisition and clogging of fish gills. Due to the lack of experience with the decommissioning of offshore wind farm components, it is difficult to quantify the amount of suspended solids that will enter the water table during this process, and thus the significance of the impact. However, the impact can be expected to be similar to or less than that occurring during construction, its nature will be moderate or spatially extensive and short-lived.

7.3.2. Release of pollutants and nutrients from the sludge into the water body

The appearance of negative impacts of toxic chemicals at the decommissioning stage of the OWF may arise as a result of harmful substances entering the water along with suspended solids lifted from the bottom as a result of foundation or cable removal work. It can be assumed that the scope and materiality of these risks are, like the construction phase, low.

7.3.3. Noise and vibration emissions

A source of disturbance during the decommissioning process will be noise associated with the increased traffic of vessels involved in the dismantling of infrastructure elements. The noise source will also be the turbine structure removal work itself. Noise generated during this phase of the project may prove to be a threat to species inhabiting new habitats created after the farms are built, with most of the effects described in the section on the construction phase. Wilhelmsson et al. (2010) suggest that, assuming the use of technologies similar to those used in dismantling oil rigs (blasting, cutting), the noise generated during the work could cause death or serious injury to nearby fish.

7.3.4. Elimination of the "artificial reef"

It is assumed that wind turbine generators should be removed in their entirety, and foundations should be removed up to 3 meters below seabed level. The cables can be removed from the bottom or left covered under a layer of sediment. If erosion protection is used, it is not recommended to remove it. The remaining technical infrastructure should be removed.

During the construction phase, there is irreversible destruction of relatively small areas. Removal of the OWF infrastructure will result in the destruction of the habitat created during construction and developing or remaining in equilibrium, created by the hard substrate-providing structural elements (Spanggaard, 2006). Thus, we can expect the disappearance of the artificial reef effect involving a decline in the abundance and diversity of ichthyofauna, as well as a deterioration of conditions favorable for the reproduction and development of early life stages of fish.

The removal of the turbine structures and other infrastructure will also make it possible to restore fishing in the area, which was closed during operation, and lift navigational restrictions. Thus, these areas will no longer be similar in their role to Marine Protected Areas (Inger et al., 2009).

Thus, it can be assumed that habitat changes caused by the decommissioning of the OWF will cause a negative effect by destroying the habitat that provides favorable breeding and living conditions for many species of ichthyofauna. The extent of this impact will be local but long-term.

7.3.5. Summary

A summary of the potential impacts of the OWF decommissioning phase on ichthyofauna is provided in the table below. The table also includes a description of potential unplanned impacts.

Table 10. Potential impacts of OWF on fish - decommissioning stage

Type of emission or disturbance	Rationale for selection and key parameters and factors affecting the level of impact
Increase in the concentration of suspended solids in water	During the decommissioning phase, operations to remove turbines, foundations and cables may increase the amount of suspended solids in the water table. The most important parameters affecting the level of impact are: • the type, dimensions and number of decommissioned foundations and the length of decommissioned cables, • a type of rock material that forms the seabed.
Release of pollutants and nutrients from the sludge into the water body	Violation of the structure of bottom sediments will result in the passage of the pollutants and nutrients they contain into the water body. These substances can negatively affect ichthyofauna. The most important parameters affecting the level of impact are: • dimensions and number of decommissioned foundations and length of decommissioned cables, • the types and amount of pollutants deposited in bottom sediments, • a type of rock material that forms the seabed.
Noise and vibration emissions	During the decommissioning phase of an offshore wind farm, noise and vibration arise from the demolition of wind turbine structural components and are associated with ship operations.

Type of emission or disturbance	Rationale for selection and key parameters and factors affecting the level of impact
	The impact of these sounds on the physiological state of the fish is the same as during the construction phase of the farm.
Habitat changes - decommissioning "artificial reef"	A micro-ecosystem of "artificial reefs" on the hard substrate of wind turbine structures will already be formed during the operation of the farm. During the decommissioning stage, elements of the OWF may be removed or left in the seabed. If elements of the farm are left in place, the impact will be no different from that during the construction phase. If the farm's facilities are removed, not only will the habitat of lichen organisms be destroyed, but also the potential habitat, feeding, shelter and breeding grounds of many fish species. The most important parameters affecting the level of impact are the diameter of the base and the number of foundations, as well as the length of the cables.
Oil spill	See description for construction phase
Contamination of water depths and bottom sediments with antifouling agents	See description for construction phase
Accidental release of municipal waste or domestic sewage	See description for construction phase
Accidental release of chemicals and waste from farm decommissioning	During the decommissioning of the wind farm, waste directly related to the decommissioning of the wind farm will be generated on the vessels, at the facilities located onshore (at the port handling the decommissioning of the project) and at the project site. These may include damaged parts of farm components, operating fluids, etc. They can be accidentally released into the sea. The most important parameters affecting the level of impact are: • the type and amount of waste or wastewater released, • weather conditions, • a type of rock material that forms the seabed.

8. Species under evaluation

This chapter briefly characterizes the ichthyofauna found in the area of the proposed OWF BIII. A full characterization is provided in the results of the study, conducted by the Marine Fisheries Institute - National Research Institute, which constitutes Section 7 of Volume III of the EIA. In addition, the chapter defines the sensitivity of selected fish species to the most important impacts of the farm and indicates their importance to the ecosystem.

The results of the study indicate that the site of the proposed farm is of little importance to fish. This is also confirmed by the relatively small commercial fishery conducted in the area of the Project.

During the surveys conducted in 2016-2017, 19 fish taxa were caught in the body of water adjacent to the Project, intended for the Baltic offshore wind farm, of which the permanent fish assemblages of the study area included cod, flatfish, herring, sprats, as well as sparse hen devils, tassels, sandeels and eels. In the ichthyoplankton samples, 12 taxa were identified. During the survey, 27 gobies larvae were recorded, most likely belonging to the small gobies, as well as 16 dennettle larvae. The results of the study are similar and indicate no significant changes in the characteristics of the area.

In the period from the issuance of the DWA to the date of this Report, no projects have been implemented or are being implemented in the BIII OWF area or its vicinity that could change the characteristics of the status of ichthyofauna presented above.

8.1. Basic characteristics of ichthyofauna in the area of the proposed farm

According to the results of ichthyofauna monitoring, 19 fish taxa were present in the area of OWF BIII and its buffer zone. The pelagic trawl and bottom set surveys recorded the presence of 15 fish species, while 10 species of fish larvae and sprat eggs were recorded in ichthyoplankton samples collected with Bongo nets (including 3 species not found in the trawl and bottom set surveys, see Table 10). Due to the difficulty in determining the larvae of sandeel and gobies to the species level, they were designated to the family.

From the point of view of the natural values of the Project area, an important result of the ichthyoplankton surveys was the presence of larvae of two fish species under partial species protection: denfish and goby larvae (most likely belonging to the small goby), found in numbers of 25 pieces and 9 pieces, respectively.

Table 11. List of fish species caught in the area of OWF BIII and the buffer zone in October 2012 - September 2013.

*Due to the difficulty in determining the larvae of sandeel fish to the species level, they were determined to the family level. There are two species of this family in the South Baltic: tobias and sandeel (both found in adult form during the survey in the study area) .

**Because of the difficulty in determining gobies fish larvae to the species level, they were determined to the family level. Taking into account the biology and environmental preferences of goby fish species found in the Baltic Sea, it can be assumed with high probability that the larvae caught belonged to the small goby species (Pomatoschistus minutus).

8.2. Sensitivity of ichthyofauna to potential impacts of the project

The sensitivity of individual species to impacts associated with subsequent phases of the project will differ. The greatest impact is on juvenile forms of the fish, as adults are more resistant to harmful factors that may be present in the environment (Knudsen et al., 1992; Wahlberg and Westerberg, 2005).

An assessment of the degree of vulnerability (sensitivity) of selected species to potential impacts of the wind farm is presented in tabular form, using a three-level scale, based on Bergstrom et al. (2014), using experience from the construction and operation of other wind farms in the Baltic Sea.

The analysis refers to the impact of the BIII OWF, distinguishing at which stage the impact occurs (construction, operation, or dismantling):

- high sensitivity defines the type of impact that affects both the abundance, distribution of fish species and the trophic network,
- medium sensitivity defines the type of impact that affects the abundance and distribution of species, but does not affect the trophic network,
- low sensitivity defines the type of little or no impact on the distribution and abundance of individual species.

An assessment of the degree of sensitivity to the potential impact of an offshore wind farm on selected fish species during the construction, operation and decommissioning stages is presented in the tables below (Tables 14- 16).

8.2.1. Sensitivity to construction stage impacts

During the construction phase of the offshore wind farm, fish may be sensitive to increased suspended solids in the water tone, water pollution, acoustic disturbance, creation of a spatial barrier, and habitat alteration. Increased suspended solids in the water depths can significantly affect early life stages of fish due to the limited possibility of avoiding the adverse effects of this factor. Pelagic eggs may be adversely affected by suspension (sinking to the bottom). In the case of adult forms, there is generally an avoidance effect (with concentrations of suspended solids generated during the construction of the OWF).

Despite the potentially high sensitivity of fish to chemicals, the risk of releasing larger quantities of harmful substances from sediments during construction activities is low due to the low concentrations found in sediments in the South Baltic. Toxic emissions from ships will not noticeably raise chemical levels in South Baltic waters, while the risk of emissions in the event of a collision has been estimated as low.

Acoustic interference is ranked among the most important negative factors affecting ichthyofauna. Noise can significantly adversely affect the development and life of fish. Noise levels associated with

foundation construction can reach 260 dB re: 1 µPa2s and cable laying work can generate noise as high as 178 dB re: 1 µPa2s. However, noise-induced mortality was recorded only within a few meters of the sound source. The sounds and vibrations generated by the construction of the OWF induce fish to leave their feeding grounds, hiding places and change their spawning territory (Slotte et al., 2004), thus affecting the survival rate of individuals and their reproductive success.

The creation of a spatial barrier during the construction phase will be relatively short, and in addition, fish actively move to avoid the barrier.

Habitat changes caused by the construction of the wind farm may affect ichthyofauna through changes in bottom morphology and sediment character, directly affecting the living and reproductive conditions of ichthyofauna and, indirectly, through the impact of habitat changes on benthic organisms that are the food source of fish. Due to the short-term nature of the impact, sensitivity is described as low for all species.

The sensitivity of ichthyofauna to the impacts of the construction phase is shown in the table below.

Table 13. List of selected fish species with assessment of the degree of sensitivity to potential impacts of OWF BIII at the construction stage

Source: Nermer T., Drgas A., Janusz J., et al. "Monitoring of ichthyofauna of the area of the offshore wind farm Central Baltic III. Final Report with Impact Assessment," Marine Fisheries Institute - National Research Institute, Gdynia, 2015.

8.2.2. Sensitivity to the impacts of the operation stage

During the operation stage of the OWF, fish may be sensitive to increased suspended solids in the water tone, water pollution, acoustic disturbance, creation of a spatial barrier, habitat alteration, and electromagnetic fields.

At the operation stage, the only sources of **toxic chemicals** that could potentially affect ichthyofauna are spills of harmful substances from ships during the maintenance and servicing of the OWF or potentially spills from the failure of the marine substation (MSE). The risk of pollution and the scale of emissions during the operation of the OWF (based on the literature) mandates that the degree of sensitivity of all species be described as low.

The level of **noise** intensity generated by wind turbines depends on the type of turbine, wind speed, the number of operating turbines and their mutual distances, as well as local hydrological, geological, depth and natural background noise conditions. The frequency of sound generated in the water by an operating turbine ranges from 1-400 Hz and the level from 80-100 dB 1µPa2s and increases with the number of turbines (Nedwell et al., 2003). Due to the low frequency and intensity of the noise, there is no danger of permanent damage to hearing organs or fish tissues as a result of noise generated by operating wind turbines. Experimental studies have shown that the noise is not strong enough to elicit an avoidance response from the fish. Therefore, sensitivity was rated as low.

The presence of windmill structures may provide a small degree of **underwater physical barrier to fish migration. It should be noted that fish actively move to avoid the barrier.**

Usually, the appearance of new structures that provide hard substrate and provide refuge for fish results in an increase in the abundance of some fish species, and biodiversity may also increase. The structures of windmill structures can be both places of refuge and places of reproduction or development of the early stages of many fish species. An additional influence is the shutdown of fishing, but this factor has a local impact. Higher sensitivity of this factor has been attributed to fish to which a **change in habitat** through the creation of an artificial reef will create more favorable conditions for reproduction (bottomfish, gobies), or shelter (cod).

Knowledge about the effects of **electromagnetic fields** on fish is relatively limited. The effects of electric and magnetic fields on some fish species, considered sensitive, have been observed. It is presumed that the electromagnetic field observed around the connection cables may also affect the migratory abilities of fish, although studies conducted on the impact of the power cable connecting Poland and Sweden (SwePol Link) have not shown a significant effect of this factor on salmonids, flatfish and juvenile cod.

The sensitivity of ichthyofauna to the impacts of the operation stage is shown in the table below.

Table 14. List of selected fish species with assessment of the degree of sensitivity to potential impacts of OWF BIII at the stage of operation

8.2.3. Sensitivity to the impacts of the decommissioning stage

During the decommissioning phase of the offshore wind farm, fish may be sensitive to increased suspended solids in the water tone, water pollution, acoustic disturbance and habitat changes.

It can be assumed that there are similar potential risks associated with an increase in suspended solids concentration to those occurring during the construction phase, such as negative effects on larval and egg development, impediments to food acquisition and clogging of fish gills.

The appearance of negative impacts of toxic chemicals at the decommissioning stage of the OWF may be related to leakage from ships or equipment involved in laying cables, and as a result of harmful substances entering the water along with suspended matter lifted from the bottom as a result of foundation or cable removal work. It can be assumed that the scope and materiality of these risks are, like the construction phase, low.

The source of acoustic disturbance during the decommissioning process will be noise associated with the increased traffic of vessels involved in the dismantling of infrastructure elements. The noise source will also be the turbine structure removal work itself. Noise generated during this phase of the project may prove to be a threat to species inhabiting the new habitats created after the farm's construction, with most of the effects described in the section on the construction phase.

Removal of the OWF infrastructure will result in the destruction of the habitat created during construction and developing or remaining in equilibrium, created by the hard substrate-providing structural elements (Spanggaard, 2006). Thus, we can expect the disappearance of the artificial reef effect involving a decline in the abundance and diversity of ichthyofauna, as well as a deterioration of conditions favorable for the reproduction and development of early life stages of fish.

8.3. Importance of ichthyofauna

Of the 19 taxa observed during ichthyofauna monitoring, 6 are of particular economic importance, being subject to commercial fishing. These include the sprat Sprattus sprattus, herring Clupea harengus, cod Gadus morhua, flounder Platichthys flesus, plaice Pleuronectes platessa and turbot Scophthalmus maximus. In research catches conducted in the area of the OWF and the buffer zone, the most abundant were sprat, herring, cod and flounder, which are also the basis of commercial fishing (more than 96.2% of total Polish marine catches in 2013).

In 2015-2020, commercial fishing, in the area of Baltic squares M7, M8, N7, N8 falling within the Project area, was dominated by cod (42% of the total weight of fish caught), flounder (23%), sprat (16.0%) and herring (14%).

In addition, during monitoring surveys, the presence of 9 goby larvae was recorded in ichthyoplankton samples, most likely belonging to the protected species of small goby Pomatoschistus minutus, as well as 25 larvae of the denning bird Liparis liparis liparis, which is also partially protected in Poland.

The above-mentioned species, due to their high importance in ecosystem functioning, relevance in commercial fisheries and legal protection status, will be included in the detailed assessment of the impact of the offshore wind farm on ichthyofauna. The remaining species were represented in smaller numbers and will not be considered in the environmental impact assessment of the project.

During the surveys conducted in 2016-2017, 19 fish taxa were caught in the body of water adjacent to the Project, intended for the Baltic offshore wind farm, of which the permanent fish assemblages of the study area included cod, flatfish, herring, sprats, as well as sparse hen devils, tassels, sandeels and eels. In the ichthyoplankton samples, 12 taxa were identified. During the survey, 27 gobies larvae were recorded, most likely belonging to the small gobies, as well as 16 dennettle larvae. The results of the study are similar and indicate no significant changes in the characteristics of the area.

A classification of the importance of the resources of each species selected for evaluation is provided in the table below.

Table 17. Classification of the importance of fish species resources selected for the impact assessment of OWF BIII

Species	Importance of the resource	Justification
Small grandmother	Medium	Protected species, population status unknown, adult forms not very susceptible to impact from the project, in the case of larval forms there may be a negative impact of suspension.
Dennik	Medium	A protected, widely distributed species with a short life cycle (1-3 years). Highly susceptible to water pollution. The denning larvae drift with the current for considerable distances.
Cod	Large	A commercially exploited species of one of the key importance for the functioning of the ecosystem, it is abundant in the Baltic Sea, although heavily subjected to anthropogenic pressure, hence the marked fluctuations in the status of the stock over recent years.
Plaice	Small	A commercially exploited species. Occurring in large numbers, it is not very susceptible to changes in the environment and can adapt quickly to any changes. The results of survey fishing confirm the presence of plaice in the

Species	Importance of the resource	Justification
		study area, but the number of individuals indicates the low importance of the OWF area for this species.
Skarp	Medium	A commercially exploited species. It occurs in lower numbers than flounder. It feeds mainly on small fish, so it is classified as a predator at the top of the ecosystem's trophic pyramid.
Orchid	Medium	A commercially exploited species. An abundant, ecosystem-important key bentophage in the southern Baltic Sea zone.
Sprat	Medium	A commercially exploited species. Abundant, of ecosystem importance. A pelagic, thermophilic species, distinguished by its relatively high mobility, determined mainly by water temperature.
Herring	Medium	A commercially exploited species. Abundant, of ecosystem importance. It is among the species with the greatest migratory tendencies between breeding and feeding sites.

Source: Nermer T., Drgas A., Janusz J., et al. "Monitoring of ichthyofauna of the area of the offshore wind farm Central Baltic III. Final Report with Impact Assessment," Marine Fisheries Institute - National Research Institute, Gdynia, 2015.

9. Assessment of the impact of OWF BIII on fish

Depending on the stage of the project, different aspects of the impact of the OWF on ichthyofauna should be considered. Potentially, the construction phase will have the greatest impact on the environment. The detailed impact of these factors on ichthyofauna is discussed in Chapter 7. Based on the analysis, it is judged that the most significant impacts are those in the form of noise and vibration, as well as the effects of an increase in the concentration of suspended solids in water.

As a result of ichthyofauna surveys conducted in the area of the planned OWF Central Baltic III and in its vicinity as part of the Pre-Investment Survey Program, 19 fish species (total adults, larvae and eggs) were found: beluga, stickleback, coalfish, demersal, sandeel, cod, plaice, devil hen, mackerel, mothership, horse mackerel, turbot, flounder, sprat, herring, tasha, tobias, eelgrass, sandeel, goby (due to difficulties in determining larvae as to species, sandeel and goby were determined as to family). A total of 1,627 fish larvae belonging to 10 species or families were caught, with the vast majority belonging to sprat (1,396 fish) and 1,762 egg grains belonging mainly to sprat.

In the research catch of adult fish, sprats (77.9%) were the most abundant species found in the OWF and buffer zone, followed by cod (9.5%), herring (7.6%) and flounder (4.4%). No adult protected or endangered fish species were found.

From the point of view of the natural values of the Project area, an important result of the ichthyoplankton surveys was the presence of larvae of two fish species under partial species protection: denfish and goby larvae (most likely belonging to the small goby), found in numbers of 25 pieces and 9 pieces, respectively.

The results of the study indicate that the site of the proposed farm is of little importance to fish. This is also confirmed by the relatively small commercial fishery conducted in the area of the Project.

During the surveys conducted in 2016-2017, 19 fish taxa were caught in the body of water adjacent to the Project, intended for the Baltic offshore wind farm, of which the permanent fish assemblages of the study area included cod, flatfish, herring, sprats, as well as sparse hen devils, tassels, sandeels and eels. In the ichthyoplankton samples, 12 taxa were identified. During the survey, 27 gobies larvae were recorded, most likely belonging to the small gobies, as well as 16 dennettle larvae. The results of the study are similar and indicate no significant changes in the characteristics of the area.

In the period from the issuance of the DWA to the date of submission of this application, no projects have been implemented or are being implemented in the area of the OWF Central Baltic III or in its vicinity, which could cause a change in the characteristics of the state of ichthyofauna presented above.

9.1. Construction phase

During the construction of OWF BIII, works will be carried out that have a direct or indirect impact on ichthyofauna. The most significant of these are:

- drilling performed during geotechnical studies,
- preparation of the bottom prior to the installation of the foundation, including dredging of the bottom, removal of the sediment layer with a thickness of about 2 - 3 m and replacing it with rock material with a higher bearing capacity (only in the case of gravity foundations, which can be used in the currently proposed variant of the Project only for supporting infrastructure),
- drilling or driving foundations (only in the case of monopiles, jacket or tripod foundations, while in the currently requested variant of the Project tripod foundations can be used only for supporting infrastructure),
- anchoring jack - up platforms and support units during the assembly of farm components,
- burying cables in the seabed,
- heaping of rock material serving as protection against leaching,
- storage of excavated material from the preparation of the bottom for foundations.

A full description of the construction work can be found in Section 4 of Volume II of the EIA.

The following impacts on ichthyofauna are expected to occur at the construction stage of OWF BIII:

1) an increase in the concentration of suspended solids in water,
2) the release of pollutants and nutrients from the sediment into the water body,
3) noise and vibration emissions,
4) the formation of a mechanical barrier,
5) habitat change.

There may also be unplanned impacts during the construction of the farm, particularly contamination of the water table and bottom sediments:

1) petroleum substances,
2) antifouling agents,
3) accidentally released municipal waste or domestic sewage,

4) accidentally released chemicals and waste from the construction of the farm,

5) blow-ups or explosions of unexploded military munitions that may indirectly affect fish.

Unplanned impacts on ichthyofauna also include those associated with the possible detonation of conventional weapons residues deposited in the sea, and which will be found during preparatory or construction work during the implementation of the Project. Decommissioning of UXO will be carried out only in cases where it is necessary.

Unplanned impacts are assessed in Chapter 11.

9.1.1. Increase in the concentration of suspended solids in water

The increase in suspended solids concentration due to the BIII offshore wind farm construction activities may affect both adult fish and juvenile stages. There may be an effect of avoidance of this area by representatives of some fish species, while others are resistant to the increase in suspended solids concentration.

Once the adverse factors have subsided, adult fish can return to previously inhabited sites (Spanggaard, 2006). Thus, the greatest impacts are associated with the early life stages of fish.

As indicated in the 2015 EIA Report, it was assumed that the largest area of the seabed would be disturbed if gravity foundations were used in the project. With the changes planned to be implemented, this type of wind turbine foundation technology has been ruled out. At the stage of issuing the DWA, a variant was analyzed in terms of the area of seabed disturbance, which, assumed the seabed disturbance to a greater extent both in terms of total area and area per wind turbine. This variant was indicated for implementation by the Environmental Decision.

Assuming that the bottom area disturbed by the laying of internal power cables will be the same for the variant indicated for implementation in the Environmental Decision and the variant envisaged for implementation after its amendment, the parameters related to the number and type of foundations envisaged for implementation after the amendment and the bottom area disturbed at the installation area of one foundation will be important for the scale of impacts.

If the requested amendments to the Environmental Decision are made, the parameters related to the foundation of the BIII OWF will be as follows:

Table 17. Parameters of the seabed disturbance area after the amendment of the Environmental Decision

Parameter	The project after the proposed modification	The project in the parameters approved Environmental Decision	The project in the NIS 2015 variant
Number of power plants	60	120	200
Maximum number of foundations (power plants and substations)	61 (including one station)	126 (including 6 stations)	208 (including 7 stations and one additional foundation)
Diameter of the base of the power plant foundation	10 m	40 m	40 m
The width of the leaching protection layer from the	20 m	15 m	15 m

Parameter	The project after the proposed modification	The project in the parameters approved Environmental Decision	The project in the NIS 2015 variant
edge of the power plant foundation			
Diameter of the base of the substation foundation	50 m	50 m	50 m
The width of the leaching protection layer from the edge of the substation foundation	15 m	15 m	15 m
Bottom surface disturbed during the installation of one power plant foundation with a leaching protection layer	1963^{m2}	3848^{m2}	5027^{m2}
Maximum bottom area occupied by 1 foundation of supporting infrastructure including a leaching protection layer	1963^{m2}	3848^{m2}	5027^{m2}
Maximum bottom area occupied by all foundations including leaching protection layers	122 807^{m2}	663 402^{m2}	804 234^{m2}
Total length of sections of internal power cables	200 km	200 km	200 km
Cable trench width	1,5 m	1,5 m	1,5 m
Bottom surface disturbed when laying internal power cables	300 000^{m2}	300 000^{m2}	300 000^{m2}
Total bottom surface area disturbed when installing all foundations including leaching protection layers and when laying internal power cables	419 744^{m2} (0.42 ^{km2})	933 402^{m2} (0.93 ^{km2})	1 092 688^{m2} (1.09 ^{km2})

It should also be pointed out that the total area of the farm is about 117 square ^{kilometers}, of which the development area will be no more than 94 square ^{kilometers}, within which it will be possible to plant wind turbines (power plant development area) on an area of about 88 square ^{kilometers}. Referring to the set of parameters that constitute the most far-reaching scenario - the 2015 NIS - it assumed a breach of 1.09 km2 of bottom. Both the variant indicated for implementation by the Environmental Decision, and even more so the Project in the proposed modified parameters, will generate significantly less impact. This is because it should be pointed out that the area of the bottom disturbed with the installation of all foundations in the variant after the requested changes will be reduced many times, which is due to the limitation of the considered foundation technologies to the installation of monopiles and jacket

foundations. Moreover, the exclusion of gravity foundations, the installation of which requires prior dredging, for wind turbines will significantly reduce the agitation of bottom sediments during the construction phase of the Project.

It was already indicated in the 2015 Report that in the case of using other types of foundations than gravity, this area will be even smaller (cf.: technical parameters of foundations, section 3.1. above). Which means that in the case of the changes proposed for implementation, impacts related to foundation placement and seabed disturbance will be significantly less than in the case of the 2015 NIS, as well as the variant envisaged for implementation by the Environmental Decision.

The assessment presented in the 2015 Report used the suspended solids spread model for this stage made by DHI and found in Section 11 of Volume II of the EIA. Modeling was done for both the then selected alternative (subsequently approved by the Environmental Decision) and the then rational alternative (NIS 2015).

The sediment transport model showed that during the construction of the OWF BIII farm, the concentration of suspended matter resulting from the works (without natural background) in the variant to be implemented under the Environmental Decision will not exceed 20 mg/l in most of the farm area and 10 mg/l outside the farm boundaries. It should be noted that in most of the analyzed basin these concentrations will be much lower, as shown in the figures below. Only at points is the concentration of suspended solids higher.

It should also be remembered that the specified concentrations will be very limited in time and space, and will only occur if gravity foundations are used on the farm, which require dredging and leveling of the seabed, and only during dredging operations. With other types of foundations, these impacts will be many times smaller.

Figure 3. Spreading range of suspended solids formed by the agitation of bottom sediments during dredging operations and their maximum concentrations near the bottom in the variant envisaged for implementation in the Environmental Decision

Source: hydrographic modeling results report (Volume II Section 11 of the EIA)

In addition, the relatively high velocity of currents observed during the study, averaging about 0.1-0.2 m/s and a maximum of about 0.5 m/s, will promote the dilution of suspended solids (source: hydrographic modeling results report, Volume II Section 11 of the EIA).

Such concentrations of suspended solids can adversely affect the early juvenile stages of fish. Literature data presented in Chapter 7 indicate that increased mortality of cod and herring larvae can be expected at suspended solids concentrations of about 10 mg/l, which is the concentration predicted for the BIII OWF construction stage (maximum 20 mg/l). A possible effect of the increased suspended solids concentration could therefore be increased mortality of herring larvae, although studies have shown little relevance of this area as a spawning ground for this species. For environmental reasons (too low salinity), cod spawning is not observed in this area (spawning grounds are mainly in the Bornholm Deep).

Due to the spawning of sprats in the study area, the effect of suspension on the pelagic eggs of this species can be significant due to a decrease in the buoyancy of the eggs and their sinking and dying on the bottom. The lowest level for which such a phenomenon was observed for pelagic eggs was 5 mg/L (Rönnbäck and Westerberg, 1996). The region of IMF BIII during the second spawning phase of the sprat (in late spring and early summer) lies directly in the spawning area of this species (Mankowski, 1959, 1972, 1978; Grauman, 1975; Elwertowski, 1976; Aro 1988, 1989). During late spring and summer, intensive surface spawning of sprats takes place throughout the southern Baltic. However, the OWF area is a small body of water, compared to the extensive spawning area of sprat, so its importance for the population of this species is not significant.

In the case of flounder, the offshore winter flounder region lies on the migration route of flounder from feeding grounds located in shallow coastal waters to spawning grounds in the Slupsk Trough, but is not a target spawning ground for the dominant deep-sea spawning flounder in the area due to the prevailing hydrological conditions here - salinity is too low, not exceeding 7.7 PSU.

An important, from the point of view of the natural values of the area of the planned project, the result of ichthyoplankton studies was the finding of the larvae of two protected fish species: denfish and small goby. A total of 13 and 12 demersal larvae and 4 and 5 goby larvae were caught in the farm and buffer zone, respectively, during the survey cycle. The numbers of larvae of both species showed no significant differences in terms of their distribution between the study areas. For some time after hatching, the larvae of both species lead a pelagic lifestyle. The presence of scattered larvae in the water depths may indicate the spawning of these species both in and near the BIII OWF area, or it may be the result of the natural drift of larvae from other areas. Dennik, which prefers a plant substrate for spawning, is most abundant in deeper waters in the eastern part of the Baltic; it is not found in the southwestern part. The larvae of this species spread very widely in the pelagial, and are sometimes encountered near the surface of the water. The little goby prefers shallow waters with a sandy bottom covered with clam shells and rocks. Adjacent to the area of the planned project is the Slupsk Shoal, which provides more

favorable conditions for spawning denfish and goby: adequate depth and the presence of substrate that allows spawning such as stones, macroalgae and empty shells.

According to the project's benthic impact assessment (Volume IV Section 3 of the ROIA), most macrozoobenthic organisms in the Project area have no or very low sensitivity to elevated suspended solids concentrations. Thus, it will not significantly affect the availability of food resources for benthic fish.

Increased concentration of suspended solids in water may cause direct negative impacts on ichthyofauna, local, short-term, reversible, repetitive (during the construction period), with low intensity.

An assessment of the significance of this impact for the set of Project parameters constituting the furthest-reaching NIS 2015 scenario that formed the basis for conducting the impact assessment in the 2015 Report is presented in the table below.

Table 18. Assessment of the impact on fish caused by an increase in suspended solids concentration in water (construction phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Cupcakes	Medium	Average	legally protected species	Negligible (scale of exposure - local, duration - short-term, intensity - low)	Negligible (magnitude of impact - insignificant, importance of the resource - medium)
Dennik	Medium	Average	legally protected species		
Cod	Large	Average	commercial genre		Small (magnitude of impact - insignificant, importance of the resource - high)
Plaice	Small	Average	commercial genre		Negligible (magnitude of impact - insignificant, importance of the resource - low or medium)
Skarp	Medium	Average	commercial genre		
Orchid	Medium	Average	commercial genre		
Sprat	Medium	Average	commercial genre		
Herring	Medium	Average	commercial genre		

Source: Nermer T., Drgas A., Janusz J., et al. "Monitoring of ichthyofauna of the area of the offshore wind farm Central Baltic III. Final Report with Impact Assessment," Marine Fisheries Institute - National Research Institute, Gdynia, 2015.

In the variant envisaged for implementation after the proposed changes to the Project's implementation and operation conditions, significantly fewer foundations will be built than envisaged not only in the 2015 NIS, but also in the parameters of the Project approved by the Environmental Decision. As the

analyses carried out in this report, and earlier in the 2015 Report, the reduction in the number of foundations is important for the scale of impacts caused, but even more important is the change in the technology of their construction itself, which is now to use monopile or jacket (truss) foundations, with the proviso that the latter will be used only if monopiles are not technically feasible. Key to reducing the impact associated with the Project, in addition to reducing the number of foundations for the power plants, will be the fact that no gravity foundations are planned, the foundation of which involves interference with the bottom, resulting in an increase in the concentration of suspended solids in the water. It should be noted that 60 monopile or jacket (truss) foundations are planned for the Project. Thus, this method of plant foundation will significantly reduce the interference with the bottom and the possibility of sediment agitation, and consequently the level of suspended solids in the water will be lower in relation to that assumed at the stage of the 2015 Report and the variant planned for implementation by the Environmental Decision. With regard to the method of foundation of the associated infrastructure, it should be pointed out that a single foundation will be used to install it, which can be made in monopile, tripod, jacket (truss) or gravity technology. Nevertheless, it should be emphasized that it will be a single structure. Therefore, it should be considered that in the case of updating the Project's parameters, assuming the construction of 50% of the foundations for the power plants in relation to the parameters of the Project approved by the Environmental Decision and only one foundation for infrastructure (the number reduced from 6), as well as a change in the technology to be used for their construction, the Project will cause impacts on ichthyofauna of insignificant magnitude, which will have insignificant significance for the identified fish species, except for cod, for which the significance of the impact should be considered low.

Given that even with the set of parameters of the Project constituting the 2015 NIS, as well as the parameters under which it will be implemented after the amendment of the Environmental Decision, the significance of impacts associated with an increase in the concentration of suspended solids in water is considered negligible or small, **minimization measures are not required**.

Thus, it should be considered that both the nature of the impacts and their scope and magnitude are the same as for the variant approved by the Environmental Decision and the one constituting the 2015 NIS in the 2015 Report, and thus the proposed change in the parameters of implementation and operation of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.1.2. Release of pollutants and nutrients from the sludge into the water body

The disturbance of the bottom sediment layer during construction activities will also involve the release of a certain pool of pollutants and nutrients from it, which will pass into the water depths.

Research conducted directly in the area planned for the construction of OWF BIII (Research on physical and chemical conditions of sediments in the area of OWF Central Baltic III - final report, Volume III Section 5 of the ROOŚ) confirmed the low concentration of hazardous substances in the sediments (PAHs, PCBs, heavy metals, mineral oils, radionuclides). None of the sediment samples tested from the BIII offshore wind farm area exceeded allowable concentrations of metals, PAHs and PCBs. The estimate of the amount of heavy metals, pollutants and nutrients that may be released in the variant indicated for implementation by the Environmental Decision will not be significant in comparison with the loads contributed annually to the Baltic Sea from rivers and wet precipitation (cf. Abiotic Environmental Impact Assessment, Section 2 Volume IV of the EIA).

Taking into account the above research results, it can be concluded that at the stage of construction of OWF BIII there will be no significant threats to ichthyofauna associated with an increase in the concentrations of toxic chemicals released from the sediments.

The release of a certain pool of pollutants and nutrients from disturbed bottom sediments may cause direct and indirect, negative impacts on ichthyofauna, local, temporary, reversible, repetitive (during the construction period), of low intensity.

An assessment of the significance of this impact of the set of parameters of the Project constituting the 2015 NIS, is presented in the table below.

Table 19. Assessment of the impact on fish of pollutants and nutrients released from sediments into the water body (construction phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Cupcakes	Medium	Low	legally protected species	Insignificant (scale of exposure - local, duration - temporary, intensity - low)	Negligible (magnitude of impact -
Dennik	Medium	Low	legally protected species		insignificant, importance of the resource - medium)
Cod	Large	Low	commercial genre		Small (magnitude of impact - insignificant, importance of the resource - high)
Plaice	Small	Low	commercial genre		Negligible (magnitude of impact - insignificant, importance of the resource - low or medium)
Skarp	Medium	Low	commercial genre		
Orchid	Medium	Low	commercial genre		
Sprat	Medium	Low	commercial genre		
Herring	Medium	Low	commercial genre		

Source: Nermer T., Drgas A., Janusz J., et al. "Monitoring of ichthyofauna of the area of the offshore wind farm Central Baltic III. Final Report with Impact Assessment," Marine Fisheries Institute - National Research Institute, Gdynia, 2015.

In the variant envisaged for implementation after the requested amendments to the Environmental Decision, significantly fewer power plants will be built than envisaged for the set of parameters of the Project constituting the 2015 NIS, which, as can be seen from the table presented in Section 9.1.1, will translate into a smaller area of bottom violations. It should be noted that the reduction in the number of foundations is important for the scale of impacts caused, but even more important is the change in the technology of their construction itself, which is now to use monopile or jacket (truss) foundations. Key to reducing the impact associated with the Project, in addition to reducing the number of foundations for the power plants, will be the fact that no gravity foundations are planned, the foundation of which involves interference with the bottom, resulting in an increase in the concentration of suspended solids in the water. It should be noted that 60 monopile or jacket (truss) foundations are planned for the Project. Thus, this method of plant foundation will significantly reduce the interference

with the bottom and the possibility of releasing nutrients and pollutants from bottom sediments, and thus their levels will be lower relative to the variant constituting the 2015 NIS at the 2015 Report stage and the variant planned for implementation by the Environmental Decision. Regarding the method of foundation of the associated infrastructure, it should be pointed out that, a single foundation will be used to install it, which can be made in monopile, tripod, jacket (truss) or gravity technology. Nevertheless, it should be emphasized that it will be a single structure, which will be located in the central part of the farm.

With the above in mind, it should be assumed that in the case of an update of the parament of the Project assuming the implementation of 50% of the foundations in relation to the parameters of the Project approved by the Environmental Decision, as well as a change in the technology to be used for their construction.

The project will cause impacts on ichthyofauna of insignificant magnitude, which will be of insignificant importance for the identified fish species, except for cod, for which the significance of the impact should be considered low.

Taking into account the above, the Project in the variant indicated for implementation after amendment of the Environmental Decision should be considered that the significance of impacts on fish associated with the release of pollutants and nutrients from the sediment into the water body is negligible or small, and minimization measures are not required.

9.1.3. Noise and vibration emissions

The noise level associated with construction work is largely dependent on the type of foundation used. The technical concept prepared by Royal Haskoning DHV for the BIII offshore wind farm allows 4 types of them: gravity foundations (for which piling is not used) and monopiles, jacket foundations and tripod foundations. Each of these types of foundation would have been taken into account at the stage of the 2015 Report, as well as allowed by the Environmental Decision. At this stage, this environmental impact report has filed the possibilities of implementing wind power plants only on the basis of either monopile or jacket (truss) foundations, and in the case of the foundation for infrastructure: monopile, tripod, jacket (truss) or gravity.

Significant acoustic interference with foundation construction occurs with monopiles and truss (jacket) and tripod-type structures, and averages less than 170 dB, according to the cited report. Thus, they are lower than most of the values reported in the literature, for which negative effects on ichthyoplankton have been observed. However, the DHI acoustic report (Volume II Section 9 of the report) describes in detail the most far-reaching scenario, which assumes maximum sound exposure peaks of as much as 260 dB when sound waves accumulate over a 24-hour period. For the purpose of impact significance analysis, ranges of sound exposure values were adopted to determine impact intensity:

- <140 dB - low impact,
- 140-170 dB - medium impact (avoidance response),
- 170 - 210 dB - high impact (TTS - temporal shift of hearing threshold),
- 210 dB > - very high impact - (PPS - permanent shift in hearing threshold, mortality).

The DHI report prepared for the 2015 Report presented the acoustic impact ranges taken into account for the assessment conducted at the time, which took into account the assumptions in effect at the time regarding the scope and method of implementation of the project, primarily the type of foundations, their parameters and the method of installation work. This report was prepared based on the then prevailing level of knowledge and available literature.

At that stage, the assessment of the significance of this impact for the set of parameters of the Project constituting the 2015 NIS, which was the basis for conducting the assessment in the 2015 Report, **without the application of minimization measures**, is presented in the table below.

Table 20. Assessment of noise and vibration impacts on fish without minimization measures (construction phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	The rationale for impact assessments	Magnitude of impact	The significance of the impact
Cupcakes	Medium	High	legally protected species	Large (scale of exposure- international, duration- medium, intensity- medium)	Moderate (magnitude of impact - high, importance of the resource - medium)
Dennik	Medium	High	legally protected species		
Cod	Large	High	commercial genre		Large (magnitude of impact - high, importance of the resource - high)
Plaice	Small	High	commercial genre		Small (magnitude of impact - high, importance of the resource - low)
Skarp	Medium	High	commercial genre		
Orchid	Medium	High	commercial genre		
Sprat	Medium	High	commercial genre		
Herring	Medium	High	commercial genre		

Source: Nermer T., Drgas A., Janusz J., et al. "Monitoring of ichthyofauna of the area of the offshore wind farm Central Baltic III. Final Report with Impact Assessment," Marine Fisheries Institute - National Research Institute, Gdynia, 2015.

Due to the finding of high significance of noise impact during monopile driving, which was considered the most far-reaching scenario - NIS 2015 in terms of impact on ichthyofauna, among others, the Environmental Decision imposed an obligation to reduce underwater noise impact. At this stage, the zones of potential noise impact on fish have been verified. These are shown in Table 22 below. Based on these, a reassessment of the significance of the above impact was carried out. It should be recognized in this regard that the findings made at the 2015 Report stage applicable to the NIS remain valid in this regard. After the application of mitigation measures **, the scale of the impact decreased to regional, which significantly affected the assessment of the magnitude and significance of the impact**.

The assessment of noise and vibration impacts on fish for the set of parameters of the Project constituting the 2015 NIS, after the application of mitigation measures in the form of bubble curtains (so-called bubble curtains), is presented in the table below.

Table 21. Assessment of noise and vibration impacts on fish after application of minimization measures (construction phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Cupcakes	Medium	High	legally protected species	Small (scale of exposure - regional, duration - medium-term, intensity - medium)	Small (size of impact - small, importance of resource - medium)
Dennik	Medium	High	legally protected species		
Cod	Large	High	commercial genre		Small (magnitude of impact -small, importance of resource - high)
Plaice	Small	High	commercial genre		Negligible (magnitude of impact -small, importance of the resource - small)
Skarp	Medium	High	commercial genre		
Orchid	Medium	High	commercial genre		
Sprat	Medium	High	commercial genre		
Herring	Medium	High	commercial genre		

Source: Nermer T., Drgas A., Janusz J., et al. "Monitoring of ichthyofauna of the area of the offshore wind farm Central Baltic III. Final Report with Impact Assessment," Marine Fisheries Institute - National Research Institute, Gdynia, 2015.

It should be noted that the above analyses were conducted in accordance with the assumptions made for the assessment of impacts contained in the 2015 Report. The set of parameters of the Project evaluated there was the scenario for the implementation of the BIII OWF in the variant of the most far-reaching possible impacts - NIS 2015. This scenario has been adjusted to the current assumptions under which the Project is to be implemented, which have changed from those set forth in the Environmental Decision, which at this stage determines the maximum possible scope of the Project.

In view of the intention to amend the Environmental Decision, noise propagation modeling for the BIII offshore wind farm (Sound Simulation Pile Driving for Baltic WF, Equinor 2020) was conducted again in 2020. At this stage, it is assumed that the maximum diameter of monopile foundations that could be installed as part of the Project is up to 10 m (originally assumed to be 12.5 m). Currently, it is also possible to use jackhammers with a higher capacity than originally planned for the installation of foundations, which is related to the rapid development of technologies used for the construction of offshore wind farms. A description of the issues of acoustic impacts is presented in Volume II, Section 9, which presents the methods and input data used to model sound propagation during monopile driving, which is to be carried out under current assumptions. This information is included in the chapter.

For the planned Project, 60 foundations for wind turbines and 1 for associated infrastructure are assumed, with monopole foundations likely to cause the greatest acoustic impacts. The parameters of the Project approved by the Environmental Decision assumed the construction of 120 wind turbines, which could also be sited using this technology. In the case of the set of parameters of the Undertaking

constituting the 2015 NIS, it could be as many as 200 power plants. For both of these OWF implementation alternatives, based on the analyses conducted, it was shown that sound emissions did not cause significant negative impacts.

In order to verify the impact of the changes in question on the predicted ranges of underwater noise impacts on marine organisms, particularly in relation to the closest Natura 2000 area protecting marine mammals, i.e. the Ostoja Słowińska area (PLH220023), a simulation of underwater noise propagation from the piling of a 10 m diameter monopile foundation using a 4,500 kJ pneumatic hammer was carried out. The location of the foundation in the BIII OWF development area for modeling purposes was selected to be as close as possible to the boundary of the aforementioned Natura 2000 area. The modeling was performed for two scenarios - with and without the use of a single bubble curtain, which allows us to determine the predicted effectiveness of this solution in minimizing underwater noise propagation. It should be noted here that the use of a minimization measure in the form of a bubble curtain or other, no less, to reduce the spread of underwater noise, as a mandatory recommendation was included in the conclusions of the EIA Report.

With regard to ichthyofauna, a summary of the results of the conducted modeling is presented in the table below.

Table 22. The ranges of underwater noise impacts emitted during the piling of a 10 m diameter foundation with a 4,500 kJ jackhammer in the offshore wind farm BIII development area - with and without the use of a single bubble curtain, reducing the pressure level

Source	Taxonomic group	Impact [threshold value]	Modeled sound type	Range of influence (m)			
				with minimization		without minimization (for comparison purposes)	
				average	max.	average	max.

		PTS [203 SELcum24]	Multiple strikes	1634	2170	3985	4513
		TTS [186 SELcum24]	Multiple strikes	5441	6301	14394	20532

*Threshold values were adopted for the group of fish with the best-developed hearing (fish in which the swim bladder is connected to the hearing organs).

Source: own study based on the results of modeling performed for the BIII OWF project.

Considering the above, it should be stated that despite the fact that the Project update will result in the construction of significantly fewer foundations that were assumed in the 2015 NIS, as well as for the Project in the parameters approved by the Environmental Decision, the unit sound emissions caused by piling foundations under the current Project implementation assumptions will result in impacts of the same magnitude and significance as those assessed in the 2015 Report. At the same time, it should be noted that the period of exposure to this impact will be shortened, which involves fewer foundations.

9.1.4. The formation of a mechanical barrier

Any structures supporting the foundation stage of the OWF, as well as newly constructed elements of wind installations, may constitute a barrier to fish migration routes. However, they have the ability to bypass these obstacles in order to move to areas with more favorable living conditions. The density of the turbines is low enough that it will not affect the migration opportunities of ichthyofauna.

A mechanical barrier in the form of emerging foundations and other underwater objects can directly negatively affect ichthyofauna. This will be a local, temporary, reversible, repetitive (during the construction period), low-intensity impact.

An assessment of the significance of this impact of the set of parameters of the Project constituting the NIS 2015, is presented in the table below.

Table 23. Assessment of the impact of a wind farm as a mechanical barrier on fish migration routes (construction phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Cupcakes	Medium	Low	legally protected species	Insignificant (scale of exposure - local, duration - temporary, intensity - low)	Negligible (magnitude of impact - insignificant, importance of the resource - medium)
Dennik	Medium	Low	legally protected species		
Cod	Large	Low	commercial genre		Small (magnitude of impact - insignificant, importance of the resource - high)
Plaice	Small	Low	commercial genre		Negligible (magnitude of impact - insignificant, importance of the resource - low or medium)
Skarp	Medium	Low	commercial genre		
Orchid	Medium	Low	commercial genre		
Sprat	Medium	Low	commercial genre		
Herring	Medium	Low	commercial genre		

Source: Nermer T., Drgas A., Janusz J., et al. "Monitoring of ichthyofauna of the area of the offshore wind farm Central Baltic III. Final Report with Impact Assessment," Marine Fisheries Institute - National Research Institute, Gdynia, 2015.

In the case of the Project in the parameters approved by the Environmental Decision, far fewer foundations will be built than envisioned in the set of Project parameters constituting the 2015 NIS, so they will be even less of a barrier to fish. Therefore, it was considered that this option would result in lower impacts on ichthyofauna than the set of parameters of the Project constituting the 2015 NIS.

Considering that even with the set of parameters of the Project constituting the NIS 2015, the impact of the mechanical barrier on fish is negligible or small, **minimization measures are not required**.

In view of the above, it should be considered that updating the parameters of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings that resulted in the Environmental Decision.

9.1.5. Habitat changes

Construction work will lead to the complete destruction of the benthos in the areas of excavations for foundations and trenches where cables will be run. This will deplete food resources for benthic fish. However, the area where habitat alteration will completely eliminate benthic organisms will be relatively small (about 1% of the total project area for the set of Project parameters provided in the 2015 NIS). Detailed calculations of the benthic biomass that could potentially be lost due to construction

activities are presented in Chapter 9.2 of the Benthic Impact Assessment (Volume IV Section 3 of the EIA). This will be about 760 Mg, most of which will be the biomass of the mussel overgrowing the stonewort area that makes up 48% of the BIII OWF area - the figure for the 2015 NIS.

Taking into account the above data, the predicted rapid rate of recovery of the benthic population (cf. the chapter "Establishment of the artificial reef" later in this paper), and the fact that fish actively move in search of food, such a loss of organisms included in the diet of benthic fish can be considered insignificant.

Also, the reduction in the food base of fish caused by the negative impact of covering the bottom with a layer of fine sediment settling from the water depths should not be significant. In the variant approved by the Environmental Decision, these values are 1 mm (within the area) and 0.4 mm (outside its borders), respectively. It should also be borne in mind that this sediment will not be stable and, over time, will be further dispersed under the influence of ocean currents (cf. Hydrographic modeling results report, Volume II Section 11 of the EIA). However, such a relatively small change in habitat can disrupt the development of benthic eggs (herring, bottomfish, gobies) by covering already deposited grains or hindering their deposition on the altered sediments. However, the extent of such impact will be local and can be considered insignificant.

The results of the zoobenthos structure and its susceptibility analyses (Volume III Section 6 and Volume IV Section 3 of the ROOŚ) indicate that organisms, which are a component of the diet of benthic fish such as clams and crustaceans, are not sensitive to its impact (cf: Monitoring of ichthyofauna of the area of the OWF Central Baltic III - Final report with research results, Volume III Section 7 of ROOŚ). Thus, there is no basis for assuming that the impact of sedimentation of sediment from the water depths will significantly reduce the food base of benthic fish.

Habitat changes caused by construction activities may directly or indirectly adversely affect ichthyofauna, especially benthic and bottom spawning fish. This will be a local, temporary, reversible, repetitive (during the construction period), medium intensity impact. An assessment of the significance of this impact for the set of Project parameters constituting the 2015 NIS is presented in the table below.

Table 24. Assessment of impact on fish of habitat alteration due to seabed construction activities (construction phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Cupcakes	Medium	Low	legally protected species	Negligible (scale of exposure - local, duration - short term, intensity - medium)	Negligible (magnitude of impact - insignificant, importance of the resource - medium)
Dennik	Medium	Low	legally protected species		
Cod	Large	Low	commercial genre		Small (magnitude of impact - insignificant, importance of the resource - high)
Plaice	Small	Low	commercial genre		Negligible (magnitude of

For the Project, significantly fewer power plants will be built under the updated parameters. In the variant approved by the Environmental Decision, 120 were envisaged for implementation, and after the changes, the number will be no more than 60, which is far less than envisaged in the 2015 NIS (70%), so the habitat changes will be of a smaller scale. In addition to reducing the number of power plants, a significant reduction in the impact will also be affected by limiting the types of foundations that can be used for power plant foundations (to monopile or jacket foundations). It is therefore considered that the Project after the proposed modifications will cause lesser impacts on ichthyofauna than the Project in the parameters constituting the 2015 NIS and as approved in the Environmental Decision.

Thus, it should be considered that both the nature of the impacts and their scope and magnitude are smaller than in the case of the variant approved by the Environmental Decision, and thus the updating of the parameters for the implementation and operation of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

Given that even for the set of parameters of the Project constituting the 2015 NIS, the significance of impacts related to habitat alteration is negligible or small, **minimization measures are not required**.

9.1.6. Cumulative impact

Assumptions for analyses of cumulative impacts of OWF BIII and other projects on ichthyofauna are presented in Chapter 3. On the other hand, a broad description regarding this issue can be found in Section 13 of Volume II of the EIA.

At the stage of construction of the BIII offshore wind farm, cumulative impacts may arise if installation work on several offshore wind farms proceeds simultaneously, including foundation placement, as well as as as a result of dredging the bottom for internal and external connection infrastructure cables installed in it. Cumulative impacts involve investments located close to each other.

In the case of the BIII OWF, it will be the vicinity of offshore wind farms: Baltica 2 and Baltica 3, FEW Baltic Power, and MIP BSIII.

The impact assessment conducted in the 2015 Report assumed two possible scenarios for cumulative impacts that may affect ichthyofauna.

The impact assessment conducted in the 2015 Report assumed two possible scenarios for wind farm development in the POM for cumulative impact analyses presented below:

The first assumed between 2019 and 2021, power plants with a total capacity of 900 MW will be built, including 600 MW under the BIII offshore wind farm and 300 MW under the Baltica 3 offshore wind farm. Undersea cables were also assumed for these farms. It was assumed that the average power plant would have a capacity of 6 MW, and their number was estimated at 150. Associated infrastructure (e.g., substations, social platforms, etc.) was also to be built. It was assumed that 158 foundations and about 158 km of internal cables would be installed on the seabed in this connection. This scenario has not been realized.

Subsequently, it was assumed that power plants with a total capacity of 1,350 MW would be built between 2023 and 2026, including 600 MW under OWF BIII and 750 MW under OWF Baltica 2. A total of 225 wind power plants will be built (assuming an average plant capacity of 6 MW). Associated infrastructure (substations, social and survey platforms, etc.) will also be built. It was assumed that 232 foundations and about 232 km of internal cables would be installed on the seabed in this connection.

In addition, there are heavily used shipping routes in the vicinity of the farm (including the Traffic Separation Scheme (TSS)), in the area of which the risk of oil spills increases.

After 2026, if additional connection conditions are obtained, the investor may build more power plants, with a total capacity of 600 MW, under the BIII offshore wind farm. 60 wind turbines will be built. Associated infrastructure will also be built. It was also assumed that an additional 63 foundations and about 62 kilometers of internal cables would be installed on the seabed as a result.

The second scenario that was considered was presented in the Environmental Impact Report prepared in 2015 for the BII offshore wind farm, which assumed that in 2023 - 2026 the above quantities of power plants and infrastructure would be built not in the areas of the BIII and Baltica 3 offshore wind farms, but as the BII and Baltica 2 offshore wind farms. However, such an alternative scenario did not significantly change the level of impacts.

It was then assumed that in the above scenario, the level of cumulative environmental impacts would be only 16.5% higher than the level analyzed in the report as a reasonable alternative (NIS 2015), with the assumption that the 300 MW Baltica 3 offshore wind farm would be built in 2019-2021, i.e. earlier than the stage I construction of the BIII offshore wind farm would occur.

The most significant potential impact may be the cumulative impact of noise from piling. The DHI Technical Report (see Volume II, Section 9 of the ROIA) presents this issue in 2 options: cumulation of emissions inside the project and cumulation with an external project.

In the first case, the total scale of impact of the BIII offshore wind farm is influenced by the intensity of the factor and the timing and scale of the impact. For the most part, the magnitude of the impact was described as insignificant, and the significance of the impact as low or negligible.

In the case of sound exposure, the DHI acoustic report presents a situation of cumulative impacts, in which two structures are simultaneously piled and mitigation measures are applied. In this case, the range (CPPS) will not increase significantly and will be 20-30 km from the sound source, and the avoidance response will be up to 60 km, respectively. **Given this furthest-reaching scenario of the 2015 NIS, according to the methodology, construction can be classified as: negative in nature, direct impact, regional scale, impact frequency constant, medium duration, medium intensity. Considering the Impact Significance Assessment Matrix, the impact of OWF construction will be a low impact for cod and negligible for other species.**

In the second case, assuming that the impact of the other farms is identical to OWF BIII, and that they will be built at the same time, the scale of exposure includes the regional level. Then (also taking into account the Impact Significance Assessment Matrix) the cumulative impact of all investments will be classified as low. This is confirmed by DHI's acoustic report for cumulative impacts, when the hypothetical construction of two wind farms (OWF BIII and Baltica 3) with simultaneous piling of one

structure could cause an avoidance response within a radius of up to about 60 km from the sound source, which includes only POM and ICES Area 25, which according to the accepted methodology is a regional exposure. In order for significant impacts to occur, a factor on a scale larger than regional would be required, impacting long-term with high frequency. Such impacts could occur if negative sound impacts are not mitigated during the construction of offshore wind farms or if wind farm construction is located near cod spawning zones near the Danish border.

Compared to the scenario assumptions adopted in the 2015 Report, the timing of all planned projects has changed, as they have all been delayed.

It is currently anticipated that piling of foundations at the BIII offshore wind farm can be carried out in 2023- 2025. During this period, the Baltica 2 offshore wind farm, which has a signed connection agreement with a completion date similar to the BIII offshore wind farm, may also be implemented.

From the point of view of the potential impact of construction work on fish, without a doubt the most significant impact that can cumulate is noise from piling.

It should also be noted that the assessment of the impact of piling noise on ichthyofauna was made under the assumption that successive foundations are installed one after the other, and the time between the piling process for successive turbines is too long to lead to accumulation of acoustic energy (and thus cumulative CPPS). If the time between the installation of one foundation and the next is less than 72 hours (the period during which porpoise return), cumulative impacts may occur, resulting in a barrier effect or long-term displacement from habitat.

On the other hand, theoretically, a situation could arise when 2 teams driving foundation piles work simultaneously in the BIII OWF area. It can also not be ruled out that foundation piles will be driven simultaneously in the OWF BIII and OWF Baltica projects (2). Such situations are unlikely, due to the limited availability of the specialized equipment required for this type of work, but nevertheless theoretically they could happen. An analysis of such an accumulation scenario, including the BIII offshore wind farm, Baltica offshore wind farm and BII offshore wind farm projects, was conducted as part of the environmental impact assessment of the Baltica offshore wind farm project (IMG/MEWO 2017).

When considering the potential for cumulative impacts of the Project with other projects, it should be borne in mind that the BIII offshore wind farm in its planned modified parameters assumes the construction of 60 wind power plants, which is 50% of the number of plants envisaged by the Environmental Decision and 30% of those assessed in the 2015 NIS. In addition, the modified parameters of the Project assume the abandonment of the possibility of gravity and tripod-type foundations, i.e. the solutions that have the greatest significance from the point of view of potential impacts on ichthyofauna having their source in the increase of suspended matter in the water-depth, release of toxic substances and noise emissions (construction of the OWF and foundation of transmission cables) and emission of electromagnetic fields. By the same token, it should be considered that the impacts caused by the implementation of the projects in the scenarios included in the scenarios forming the basis of the analyses adopted in the 2015 Report will not increase in the event of implementation of the Project in the proposed modified parameters, and the scenarios themselves can be considered valid for making inferences about cumulative impacts.

In addition, it should be added that due to the limited amount of specialized equipment and crews engaged to erect structures for the OWF, it is unlikely that the implementation of more than one farm can be carried out at the same time.

9.2. Operation stage

During the operation of the Project, works affecting the seabed and marine waters will be carried out in the Project area, mainly maintenance works. Among other things, their effect will be a slight disturbance of the sludge structure, causing further release of pollutants and nutrients from the sludge. In addition, small oil spills can be expected to occur during the normal operation of ships or the release of antifouling substances from their hulls. A full description of the work during the operation stage is provided in Section 5 of Volume II of the EIA.

The ichthyofauna will be impacted at the operational stage primarily by foundation structures that will occupy part of the seabed. It should be pointed out that this impact will be significantly reduced in relation to the set of parameters of the Project constituting the 2015 NIS and the variant envisaged for implementation on the basis of the Environmental Decision. This is due to both the reduction in the number of turbines and the fact that during the operation of the OWF they will be populated by benthic organisms and an "artificial reef" will be created, creating favorable conditions for fish feeding and for the development of eggs and fry.

At the stage of operation of OWF BIII, the following emissions and environmental disturbances are expected to occur, which may cause impacts on fish:

1) emissions of compounds from corrosion protection agents,
2) noise and vibration emissions,
3) the formation of a mechanical barrier,
4) the creation of an "artificial reef."
5) electromagnetic field and radiation emissions.

The detailed impact of these factors on ichthyofauna is discussed in Chapter 7 - Potential Impacts of Offshore Wind Farms.

There may also be unplanned impacts during the operation of the farm, particularly pollution of the water table and bottom sediments:

1) petroleum substances,
2) antifouling agents,
3) accidentally released municipal waste or domestic sewage,
4) accidentally released chemicals and waste from the operation of the farm, which may indirectly affect fish.

Unplanned impacts are assessed in Chapter 11.

9.2.1. Emissions of compounds from corrosion protection agents

Steel structures or foundation elements of power plants and substations will corrode in the marine environment. Accordingly, appropriate protective measures will be necessary. The most common anti-corrosion method used in the marine environment is cathodic protection. It can be implemented as galvanic or electrolytic protection.

Galvanic cathodic protection involves mounting aluminum (Al) or zinc (Zn) anodes on the foundations. The anodes are gradually consumed, and Al or Zn passes into the water depths and accumulates in the bottom sediments. In the case of electrolytic protection, such interactions do not occur. Thus, the assessment applies only to galvanic cathodic protection.

These emissions are described in detail in Section 9.2.10 of the abiotic impact assessment (Volume IV Section 2 of the EIA).

According to the results of studies of marine waters in the area of the Project, they are characterized by an alkaline reaction: pH in the range of 7.56-8.66 (Volume III, Section II). Thus, releases of aluminum from the project's galvanic cathodic protection are not expected to cause a significant increase in the concentration of toxic dissolved forms of this element (which pose a particular threat to aquatic organisms) in the vicinity of the farm's foundations. Given the hydrodynamic conditions of the body of water in the project area (open marine waters), allowing for rapid dispersion and dilution of the released substances, and the results of the studies described above (in particular, Gabelle et al. (2012)), the concentration of molecular forms in water in the vicinity of corrosion-protected structures is also not expected to increase significantly. Due to the aforementioned conditions, Al concentrations in sediments in the vicinity of the farm's foundations are also not expected to increase significantly. In doing so, it should be noted that the total Al content in bottom marine sediments is high, because since it is derived from clay minerals distinguishing the natural background of Al content in sediments from the influence of galvanic anodes on its concentration can be difficult (Kirchgeorg et al. (2018)). Taking into account the above, it can be assumed that in the water around the foundations of the planned farm there will be no formation of zones with significantly elevated concentrations of aluminum compound.

In the case of monopole foundations, it is assumed that the emission of anodic material (Al and Zn) in the case of an uncoated foundation over 25 years of operation of the farm is about 13 Mg, and 6 mg after the application of a protective coating, assuming that its damage will not be greater than 32% after this operation. In the case of the jacket foundation, these quantities are 22.5 Mg and 7.5 Mg, respectively (Kirchgeorg et al. (2018)). Based on the cited literature data, which presents the most up-to-date information on the topics of anode material releases, an estimate can be made of the amount of aluminum and zinc that will be released at the stage of operation of OWF BIII.

Table 25. Quantities of Al and Zn that may be released during 25 years of operation of OWF BIII in the variant indicated for implementation after amendment of the Environmental Decision

Type of foundation	Additional protective coating	Weight of Al-Zn anode material, including 5% Zn (Mg)	The amount of Al and Zn released		
			1 foundation, the amount of element released over the life of the farm (25 years)	Variant to be implemented after amendment of the Environmental Decision (61 foundations), the amount of element released per year by the entire farm	NIS 2015 (208 foundations), the amount of element released annually by the entire farm
Monopal	not	approx.13.0	approx. 12.35 Mg Al approx. 0.65 Mg Zn	approx. 30.13 Mg Al approx. 1.59 Mg Zn	approx. 102.75 Mg Al approx. 5.41 Mg Zn
	yes	approx. 6,0	approx. 5.70 Mg Al approx. 0.30 Mg Zn	approx. 13.91 Mg Al approx. 0.73 Mg Zn	approx. 47.42 Mg Al approx. 2.49 Mg Zn
Jacket	not	approx. 22,5	approx. 21.38 Mg Al approx. 1.13 Mg Zn	approx. 52.16 Mg Al approx. 2.75 Mg Zn	approx. 177.88 Mg Al approx. 11.06 Mg Zn

Type of foundation	Additional protective coating	Weight of Al-Zn anode material, including 5% Zn (Mg)	The amount of Al and Zn released		
			1 foundation, the amount of element released over the life of the farm (25 years)	Variant to be implemented after amendment of the Environmental Decision (61 foundations), the amount of element released per year by the entire farm	NIS 2015 (208 foundations), the amount of element released annually by the entire farm
	yes	approx. 7,5	approx. 7.13 Mg Al approx. 0.38 Mg Zn	approx. 17.39 Mg Al approx. 0.92 Mg Zn	approx. 59.32 Mg Al approx. 3.16 Mg Zn
Tripod	not	approx. 32,0	approx. 30.40 Mg of Al approx. 1.60 Mg Zn	approx. 74.18 Mg of Al approx. 3.90 Mg Zn	approx. 252.92 Mg of Al approx. 13.31 Mg Zn
	yes	approx. 10,7	approx. 83.76 Mg Al approx. 4.41 Mg Zn	approx. 24.80 Mg Al approx. 1.31 Mg Zn	approx. 696.88 Mg Al approx. 36.69 Mg Zn

As shown in Table 25, approximately 3.9 tons of Zn could be released to the environment annually if the Project is implemented after the proposed modifications in the most far-reaching scenario (tripod foundations, without additional coating). Under similar assumptions, the Project with the parameters envisioned in the 2015 NIS would have estimated Zn emissions of about 13.31 Mg/year. The 2015 Report estimated this value at a slightly lower level of 10 tons per year. However, taking into account that both estimated values of Zn releases for the 2015 NIS are negligible in relation to the load of this element entering the Baltic Sea with rivers each year - in 2006, a total of 3,157.3 Mg of Zn was discharged into the Baltic Sea with waters, of which 256.65 Mg came from Poland (HELCOM, 2011) (cf. Abiotic Environmental Impact Assessment - Volume IV Section 2 of the Report), the update of the calculations in question does not affect the result of the 2015 assessment. At the same time, it should be pointed out that even the above amounts, by releasing into the water body or accumulating in bottom sediments, may affect ichthyofauna. However, this will be an impact at the threshold of detection.

Thus, it should be considered that the nature of the impacts caused by the Project, as well as their scope and magnitude, are at a level that does not cause negative impacts on ichthyofauna. Such conclusions are also supported by the findings of the 2015 Report and the Environmental Decision issued based on it. Updating the parameters of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

Contamination of the water body and bottom sediments with compounds from antifouling agents will not affect the structure and functioning of ichthyofauna in the project area under any of the project alternatives, as shown in the table below. Minimization measures are not required.

Table 26. Assessment of impact on ichthyofauna involving contamination of water bodies and bottom sediments with compounds from corrosion protection agents (operational phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Cupcakes	Medium	Low	legally protected species	No change (no loss of the resource, no impact on the structure and operation of the resource)	No change (magnitude of impact - no change, importance of the resource - medium)
Dennik	Medium	Low	legally protected species		
Cod	Large	Low	commercial genre		No change (magnitude of impact - no change, importance of the resource - high)

9.2.2. Noise and vibration emissions

During the operation of the wind turbines, noise and vibration associated with the operation of the installed turbines will be emitted. The assumed noise emissions of the Royal Haskoning DHV technical concept will be only 2 dB(A) above the fish's hearing threshold.

For some fish species, for the development of which solid substrate is attractive, there may be an avoidance effect on the OWF region due to the stress caused by the constant vibration of the wind turbines (Thomsen et al. 2006).

Responses involving avoidance of passing vessels have been reported in studies conducted on Baltic populations of cod, herring and sprat, which exhibit the best sound-receiving abilities of the major species exploited by fisheries (Mitson, 1995). The response of fish to noise also depends on their physiological state. Herring, which have very good hearing, are observed to avoid sources of sound associated with ship traffic and fishing gear usually outside the spawning season (Olsen et al., 1983; Vabo et al., 2002), and this behavior changes when herring spawn (Nøttestad et al., 1996; Axelsen et al., 2000).

On the other hand, the avoidance effect of regions in the immediate vicinity of the turbine is likely, but the extent of this impact should not exceed a few meters. The avoidance response to the increased pressure associated with the generated sound occurs in a zone up to 4 meters from the turbine (Wahlberg and Westerberg, 2005). The effect associated with the response to particle acceleration caused by turbine operation has an even shorter range, reaching a distance of 1 meter.

Noise and vibration generated by operating power plants can have a direct negative impact on ichthyofauna. This will be a local, long-term, reversible, permanent (during the period of operation), low-intensity impact.

An assessment of the significance of this impact for the set of parameters of the Project constituting the 2015 NIS is presented in the table below.

Table 27. Assessment of the impact on fish of noise and vibration associated with the operation of wind power plants (operational phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Cupcakes	Medium	Low	legally protected species	Negligible (scale of exposure - local, duration - long-term, intensity - low)	Negligible (magnitude of impact - insignificant, importance of the resource - medium)
Dennik	Medium	Low	legally protected species		
Cod	Large	Low	commercial genre		Small (magnitude of impact - insignificant, importance of the resource - high)
Plaice	Small	Low	commercial genre		Negligible (magnitude of impact - insignificant, importance of the resource - low or medium)
Skarp	Medium	Low	commercial genre		
Orchid	Medium	Low	commercial genre		
Sprat	Medium	Low	commercial genre		
Herring	Medium	Low	commercial genre		

Source: Nermer T., Drgas A., Janusz J., et al. "Monitoring of ichthyofauna of the area of the offshore wind farm Central Baltic III. Final Report with Impact Assessment," Marine Fisheries Institute - National Research Institute, Gdynia, 2015.

In the **variant indicated for implementation in the Environmental Decision**, 40% fewer power plants were to be built than envisaged for the set of parameters of the Project constituting the 2015 NIS, and in the variant implemented after the amendment of the Environmental Decision as much as 70%, so the area where noise and vibration associated with their operation will occur will be proportionally smaller. It is therefore considered that the variant to be implemented under the revised Environmental Decision will result in lower impacts on ichthyofauna than assumed in the 2015 NIS. **Thus, it should be considered**

that updating the parameters of the project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings that resulted in the Environmental Decision.

Given that even in the 2015 NIS the significance of impacts related to noise and vibration emissions from operating power plants is negligible or small, **minimization measures are not required**.

9.2.3. The formation of a mechanical barrier

The presence of wind turbine structures may to a small extent constitute an underwater physical barrier to fish migration. Since the distances between the turbines will be large enough (minimum 800 m x 1200 m) that, regardless of the type of foundation used, the **migration opportunities of ichthyofauna will not be affected**.

Danish studies have shown that the existence of the OWF has no negative impact on fish migration routes (Leonhard et al., 2011).

A mechanical barrier in the form of emerging foundations and other underwater objects can directly negatively affect ichthyofauna. This will be a local, temporary, reversible, repetitive (during the construction period), low-intensity impact.

An assessment of the significance of this impact of the set of parameters of the Project constituting the NIS 2015, is presented in the table below.

Table 28. Assessment of the impact of a wind farm as a mechanical barrier on fish migration routes (operational phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Cupcakes	Medium	Low	legally protected species	No change (No loss of the resource, no impact on the structure and operation of the resource)	No change (magnitude of impact - no change, importance of the resource - medium)
Dennik	Medium	Low	legally protected species		
Cod	Large	Low	commercial genre		No change (magnitude of impact - no change, importance of the resource - high)
Plaice	Small	Low	commercial genre		No change (magnitude of impact - no change, importance of the resource - low or medium)
Skarp	Medium	Low	commercial genre		
Orchid	Medium	Low	commercial genre		
Sprat	Medium	Low	commercial genre

Herring	Medium	Low	commercial genre		

Source: Nermer T., Drgas A., Janusz J., et al. "Monitoring of ichthyofauna of the area of the offshore wind farm Central Baltic III. Final Report with Impact Assessment," Marine Fisheries Institute - National Research Institute, Gdynia, 2015.

In the case of the Project after the proposed modifications to the implementation and operation conditions, significantly fewer foundations (60) will be built than envisioned for the set of Project parameters constituting the 2015 NIS, so they will be even less of a barrier to fish. Thus, it is considered that the Project in the proposed updated parameters will cause lesser impacts on ichthyofauna than the Project in the parameters approved by the Environmental Decision, as well as the set of Project parameters constituting the 2015 NIS.

Given that even in the 2015 NIS the impact of the mechanical barrier on fish is negligible or small, **minimization measures for the Project** are **not required.**

9.2.4. The creation of an "artificial reef"

Taking into account the large share of mussels in the abundance and biomass of the benthos found in the report "Research of the benthos in the area of the OWF Central Baltic III. Final Report with Study Results" (Section 6 of Volume III of the EIA), it is expected that there will be relatively rapid overgrowth of the turbine foundation structures by this organism and other epiphytic organisms, which will create favorable feeding conditions for some flat fish and some gobies, as well as shelter areas for juvenile fish. The resulting new hard structures, both artificial and those created by the epiphytic organisms, may form a suitable additional substrate for the demersal eggs of the fish found during the survey (herring, gobies, demersal, horse mackerel, devil hens).

The largest feasible gravity foundation considered for the set of parameters of the Project constituting the 2015 NIS has a diameter of 40 m and a footprint of 1257^{m2}. Assuming the application of a 15-meter-wide leaching protection layer around it, its area will be about 3848^{m2}, and for 208 foundations (NIS 2015), it will be a total of 804,234^{m2} (0.8 ^{km2}). For the parameters of the Project approved by the Environmental Decision, the hardened area of the seabed will be a total of 633,402^{m2}, while this area for the Project, taking into account the proposed modifications, will be 122,807^{m2} (and the hardened area of the seabed will be 119,744^{m2}), which is due to the reduction in the number of power plants, the exclusion of the use of gravity foundations for the foundation of power plants, and the reduction in the number of substations to 1 unit.

At the same time, the final report on seabed surveys in the BIII offshore wind farm area (Volume III Section 3 of the report) indicates that the area of stonewalls determined from sonar images amounted to about 42 ^{km2} (the offshore wind farm area and buffer zone combined). However, a comparison of the two areas can be misleading due to the fact that in the case of stonewalls, the actual area of objects that provide hard substrate conducive to the formation of favorable spawning conditions is much smaller than the total area highlighted from sonar images. Thus, it is difficult to quantify the relative increase in the surface area of hard substrate conducive to reproduction for some fish species, such as gobies, herring and bottomfish. However, it is reasonable to assume that this may be an important factor positively influencing the spawning of these fish.

If restrictions are imposed on fishing in the OWF area and the area is excluded from navigation (which is one of the options under consideration), the pressure from both these sectors will decrease, and the

farm area may become a sanctuary for fish, both adults and their early development stages - larvae and fry. Excluding the area from fishing pressure could have a positive effect on ichthyofauna. However, the magnitude of this effect would probably not be large. Fishery monitoring in the BIII offshore wind farm area (Volume III Section 13 of the report), conducted as part of the pre-investment survey, indicates low fishery productivity in the area. At the same time, the area of the area where no fishing activities would be carried out is a fraction of a percentage of the area exploited by fishing for industrial species. Thus, it is difficult to speak of a fundamental decline in fishing pressure on commercial fish at the stock level caused by the cessation of fishing. Also, the possible improvement of conditions for spawning and development of early stages of commercial fish (herring, sprat) will have a local effect at most, given the small area of the area where no fishing activity will take place, compared to the available spawning grounds in the southern Baltic.

A greater positive impact from the cessation of fishing activities can be expected for protected species (gobies, dabbler) that spawn on the bottom. The lack of disturbance associated mainly with bottom trawling could positively affect the spawning processes of these fish. However, given the current very low intensity of fishing with these gears (e.g., in 2013, no bottom trawling was found in the area - source: Monitoring of fisheries in the area of the "Central Baltic II" offshore wind farm Final Report with Research Results - Volume III Section 13 of the report), their discontinuation would not likely have a rapid effect in the form of significantly increased spawning success. On the other hand, it can be assumed that the accumulation of even a small increase in the spawning success of gobies and demersal fish over consecutive years could result in some increase in the abundance of these species. However, it is impossible to quantify the effect of artificial reef formation on the size of fish stocks for which stock estimates exist (cod, herring and sprat). The BIII OWF area is small, while stock fluctuations throughout the Baltic depend on a number of both environmental and anthropogenic factors affecting much more broadly than a potential additional spawning area or an area excluded from fishing, which has lower fishing productivity than the average POM anyway.

The new habitat created by the construction of the OWF, characterized by the presence of hard substrate and a relatively rich food base for benthic fish, may provide a favorable habitat for the bull goby, an invasive species.

Since the first report in 1990 of the introduction of the bull's-eye goby Neogobius melanostomus with ships' ballast water into the Gulf of Gdansk, the presence of this species in the Polish Baltic zone has been reported both in deeper waters (up to 40-60 m) and in the shallow water coastal zone, in the Pomeranian Bay and the Vistula Lagoon and its tributaries.

Bullwhip is also spreading in new habitats due to its tolerance to a wide range of changing environmental conditions: depth, nature of the substrate, salinity, oxygen deficiencies and a diverse food base. Spawning of gobies takes place repeatedly in several portions throughout the season at depths of 0.2 to 1.5 meters on various substrates (Wandzel, 2003). It can live in both marine, brackish and freshwater environments (Carlebois et al., 1997).

Despite its high plasticity and tolerance to a wide range of environmental conditions, the permanent occurrence of bull's-eye gobies in the farm area seems unlikely, due to environmental requirements for the reproduction process. Although the goby's reproductive strategy - caring for eggs developing in the nest and protecting them from predators - is conducive to the species' establishment in a wide variety of conditions (Leather and Stolarski, 1996), it prefers a shallow depth at which to spawn (0.2 to 1.5 meters on various substrates, Wandzel, 2003). Such bathymetric conditions are not provided by the region envisaged for the construction of OWF BIII. It is unlikely that the planned project area will be colonized by fish migration from coastal areas due to the lack of planktonic larval stages and limited movement of adult fish. This species is not one of the good swimmers (Leather and Stolarski, 1996), and the range of migrations undertaken is short and usually does not exceed 100 m. The longest migrations

occur in late autumn and early spring, when the fish move between shallow and deep waters (Berg, 1949).

The above information indicates that successful colonization of the BIII OWF region by this species is not expected.

The creation of an "artificial reef" can directly positively affect ichthyofauna. These will be local, long-term, reversible, permanent (during the period of operation), low-intensity impacts.

An assessment of the significance of this impact for the set of parameters of the Project constituting the 2015 NIS, is presented in the table below.

Table 29. Assessment of impacts related to habitat alteration and creation of "artificial reef" on fish (operational phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Cupcakes	Medium	High	legally protected species	Insignificant (scale of impact - local, duration - long-term, intensity - low)	Negligible (magnitude of impact - insignificant, importance of the resource - medium)
Dennik	Medium	High	legally protected species		
Cod	Large	High	commercial genre		Small (magnitude of impact - insignificant, importance of the resource - high)
Plaice	Small	Average	commercial genre		Negligible (magnitude of impact - insignificant, importance of the resource - low or medium)
Skarp	Medium	Average	commercial genre		
Orchid	Medium	Average	commercial genre		
Sprat	Medium	Low	commercial genre		
Herring	Medium	Average	commercial genre		

Source: Nermer T., Drgas A., Janusz J., et al. "Monitoring of ichthyofauna of the area of the offshore wind farm Central Baltic III. Final Report with Impact Assessment," Marine Fisheries Institute - National Research Institute, Gdynia, 2015.

In the variant specified for implementation in the Environmental Decision, it is assumed to perform 60% of the power plant compared to the set of parameters of the Project constituting the NIS 2015 . In the variant to be implemented after the change in the conditions for implementation and operation of the Project specified by the Environmental Decision, as much as 70% fewer foundations will be built compared to the 2015 NIS, which will additionally be implemented using monopile or jacket technology, so the hard surface that may be subject to benthic overgrowth processes will be proportionally smaller.

Thus, it is considered that the significance of this impact for the proposed modification of the Project will be significantly less, while it will continue to have positive impacts on ichthyofauna.

Given that even with the set of parameters of the Project constituting the 2015 NIS, the impact of the artificial reef on fish is negligible or small, **minimization measures are not required**.

Thus, it should be considered that both the nature of the impacts and their extent in the case of the variant proposed in the application to amend the Environmental Decision do not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

9.2.5. Emission of electromagnetic fields and radiation

The threshold of fish sensitivity to the presence of electromagnetic fields and radiation is not well understood.

Observations involving tracking eel migration routes showed that electromagnetic fields generated by cables associated with the operation of the OWF caused only minor (up to 50 minutes) delays in migration or insignificant changes in the route, without causing interference that could significantly affect migration efficiency (Westerberg et al., 2007 after Wilhelmsson et al., 2010). Similarly, studies conducted on the impact of the power cable connecting Poland and Sweden (SwePol Link) did not show a significant effect of this factor on salmonids (Westerberg et al., 2007 after Wilhelmsson et al., 2010). Also, studies conducted in 1999-2002 by the Maritime Institute of Fisheries on the impact of the construction and operation of this undersea power transmission system between Poland and Sweden (SwePol Link) on the marine environment did not show any disturbance to the movement of flatfish and juvenile cod. Due to the paucity of information on the impact of this factor, the assessment of the impact of electromagnetic fields is subject to great uncertainty, however, it is not a factor that causes mortality and injury.

Electromagnetic fields can directly negatively affect ichthyofauna. These will be local, long-term, reversible, permanent (during the period of operation), low-intensity impacts.

An assessment of the significance of this impact for the set of parameters of the Project constituting the 2015 NIS, is presented in the table below.

Table 30. Fish impact assessment of electromagnetic fields emitted by submarine cables (operational phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Cupcakes	Medium	Low	legally protected species	Negligible (scale of exposure - local, duration - long-term, intensity - low)	Negligible (magnitude of impact - insignificant, importance of the resource - medium)
Dennik	Medium	Low	legally protected species		
Cod	Large	Low	commercial genre		Small (magnitude of impact - insignificant, importance of the resource - high)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Plaice	Small	Low	commercial genre		Negligible (magnitude of impact - insignificant, importance of the resource - low or medium)
Skarp	Medium	Low	commercial genre		
Orchid	Medium	Low	commercial genre		
Sprat	Medium	Low	commercial genre		
Herring	Medium	Low	commercial genre		

Source: Nermer T., Drgas A., Janusz J., et al. "Monitoring of ichthyofauna of the area of the offshore wind farm Central Baltic III. Final Report with Impact Assessment," Marine Fisheries Institute - National Research Institute, Gdynia, 2015.

In the parameters of the Project approved in the Environmental Decision, a similar number of power cables are planned to be laid as for the set of Project parameters constituting the 2015 NIS. Although in this case, the number of power plants is reduced, but the distance between the various elements of the farm increases, resulting in an increase in the length of individual power cables. For analogous reasons, the approximate number of cables will be laid when the parameters of the Project are updated. Therefore, it should be considered that the variant identified for implementation in the Environmental Decision, which is the alternative variant, as well as the variant envisaged for implementation after the amendment of the Environmental Decision, will cause the same impacts on ichthyofauna.

Given that, even in the 2015 NIS, the impact of electromagnetic fields and radiation on fish is negligible or small, **minimization measures are not required, and the requested change in the conditions for implementation and operation of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.**

9.2.6. Cumulative impact

Assumptions for analyses of cumulative impacts of the BIII OWF and other projects on fish are presented in Section 3.2. On the other hand, a broad description concerning this issue can be found in Section 13 of Volume II of the report.

The possible cumulative impact at the stage of operation of the BIII OWF is related to the existence of other offshore wind farms in the vicinity of the Project: BSII offshore wind farm, Baltica 2 offshore wind farm, Baltica 3 offshore wind farm, which at the stage of the 2015 Report, a total of 295 power plants with associated infrastructure were assumed to be implemented. The assumptions presented at the time indicated that they could be operated simultaneously between 2026 and 2050. After 2026, the number of total power plants in operation with connection infrastructure was assumed to increase to 355 if additional connection conditions are obtained under the BIII offshore wind farm (BIII OWF).

In the 2015 Report, another scenario was also assumed for the operation stage, which assumed that between 2026 and 2050, a total of 355 power plants and associated infrastructure would be operated under the BII OWF (BII OWF) and BSII OWF, as well as Baltica 3 and Baltica 2 OWF (similar to the scenario described in the paragraph above, but for a different distribution of turbines in the areas included in the OWF). After 2025, if additional connection conditions are obtained, the number of total power

plants and infrastructure in operation under the BIII offshore wind farm was assumed to possibly increase to 415.

Compared to the considerations related to the implementation of other OWF projects considered at the stage of the 2015 Report, a new circumstance is the fact that an environmental decision has been obtained for the FEW Baltic II project, Baltic Power, and proceedings are underway for C-Wind.

Referring to the above, it should also be pointed out that for the BII offshore wind farm in 2021, a decision was issued amending the DSU obtained for it in 2015, as a result of this amendment, 60 wind power plants are envisaged for implementation, and the accompanying infrastructure is to occupy 1 foundation.

It should be borne in mind that the BIII OWF in the planned modified parameters for implementation and operation of the Project assumes the construction of 60 wind power plants, which is 50% of the number of plants envisaged by the Environmental Decision and 30% of those assessed in the 2015 NIS. In addition, the modified parameters of the Project assume the abandonment of the possibility of using gravity and tripod foundations, i.e. the solutions that have the greatest significance from the point of view of the impacts of potential impacts on ichthyofauna due to the possibility of increasing the level of suspended solids in the water. Thus, from the point of view of the possibility of cumulative impacts caused by the BIII OWF, there is a significant reduction in these impacts, which should be taken into account in the course of proceedings on the decision on environmental conditions for the above-mentioned OWF projects.

As in the case of cumulative impacts during the construction phase, the dependence of various impacts associated with the operation of the BIII OWF itself can be assessed. In the impact assessment chapter, the most significant impact on local ichthyofauna will be habitat alteration through colonization of new structures combined with reduced fishing mortality. According to experience from other wind farms and data from the technical concept, colonization will be affected by the effect of avoiding regions in the immediate vicinity of the turbine, but the extent of this impact should not exceed a few meters. Nor are significant scaring effects and disruption of fish migration expected from electromagnetic field emissions.

Thus, the cumulative impact of the OWF can be described as: positive in nature, direct impact, local scale, frequency of impact permanent and long-term. Medium Intensity.

Considering the Impact Significance Assessment Matrix, the impact of OWF construction will be a low impact for cod and negligible for other species.

In the second case, assuming that the impact of the other farms is identical to that of the BIII OWF, and that the power and transmission cables are nonexistent, and that they will be operated at the same time, the scale of the impact may increase to a regional level. Then (also taking into account the Impact Significance Assessment Matrix) the cumulative impact of all investments will be classified as low.

In order for significant impacts to occur, it would be necessary for a factor to have an impact on a scale larger than regional, having a long-term impact with high frequency. The possibility of such an impact may occur if a significant portion of the POM is developed for OWF use, in which case there will be a significant decrease in fishing mortality if the areas are closed to fishing.

9.3. Decommissioning stage

At the decommissioning stage, as at the OWF construction stage, there are negative impacts in the form of noise and vibration, an increase in suspended solids concentration in the depths, and the possibility of toxic substances entering the water from sediments or due to accidents during the implementation of the works, as well as habitat alteration.

According to the assumptions, the decommissioning of the farm will take place after 20 years of operation. It should be taken into account that during this period there will be significant technological advances and it will be possible to avoid drastic interference with the environment, thus minimizing the negative effects of the decommissioning of the farm on ichthyofauna.

Analysis of this impact is hampered by the lack of experience in this type of project due to the early stage of offshore wind development as well as the impossibility of predicting what technologies will be available twenty or more years down the road when farm dismantling is carried out (OSPAR, 2008). Therefore, the assessment of the impact of decommissioning factors is largely in the nature of a precautionary approach assuming impacts like those of OWF construction.

A full description of the decommissioning work can be found in Section 6 of Volume II of the EIA.

At the decommissioning stage of the BIII OWF, the following emissions and environmental disturbances are expected to cause impacts on fish:

1) an increase in the concentration of suspended solids in water,
2) the release of pollutants and nutrients from the sediment into the water body,
3) noise and vibration emissions,
4) the formation of a mechanical barrier,
5) habitat modification - removal of the "artificial reef".

Unplanned impacts may also occur during decommissioning, particularly contamination of water depths and bottom sediments:

1) petroleum substances,
2) antifouling agents,
3) accidentally released municipal waste or domestic sewage,
4) accidentally released chemicals and waste from the decommissioning of the farm, which may indirectly affect fish.

Unplanned impacts are assessed in Chapter 11.

9.3.1. Increase in the concentration of suspended solids in water

The negative impact on ichthyofauna of elevated concentrations of suspended solids in water is described in the chapter on wind farm construction. Thus, it can be assumed that there are similar potential risks associated with an increase in suspended solids concentration to those occurring during the construction phase, such as negative effects on the development of larvae and eggs, difficulties in obtaining food, and clogging of fish gills. Due to the lack of experience with the decommissioning of OWF components, it is difficult to quantify the amount of suspended solids that will be released into the water depths during this process, but it is not expected to be greater than the amounts generated during the construction phase, when a much larger area of bottom sediments will be disturbed (no removal of power cables, for example, is expected).

The assessment of impacts on ichthyofauna that may occur due to the appearance of increased concentrations of suspended solids in water as a result of decommissioning work is the same as for analogous impacts during the construction phase (section 9.1.1. above). Minimization measures are not required.

9.3.2. Release of pollutants and nutrients from the sludge into the water body

The negative impact on ichthyofauna of impacts related to the release of pollutants and nutrients from the sediment into the water body is described in the section on the construction of the wind farm (9.1.2.). The appearance of negative impacts of toxic chemicals at the decommissioning stage of the OWF may occur as a result of harmful substances entering the water along with suspended solids lifted from the bottom as a result of foundation removal work. It can be assumed that the scope and materiality of these risks are, like the construction phase, low.

The assessment of impacts on ichthyofauna that may occur due to the release of pollutants and nutrients from the sediment into the water body as a result of decommissioning work is the same as for analogous impacts during the construction phase (section 9.1.2. above). Minimization measures are not required.

9.3.3. Noise and vibration emissions

A source of disturbance during the decommissioning process will be noise associated with the increased traffic of vessels involved in the dismantling of infrastructure elements. The noise source will also be the turbine structure removal work itself. Noise generated during this phase of the project may prove to be a threat to species inhabiting the new habitats created after the farm's construction, with most of the effects described in the section on the construction phase. Wilhelmsson et al. (2010) suggest that, assuming the use of technologies similar to those used in dismantling oil rigs (blasting, cutting), the noise generated during the work could cause death or serious injury to fish in the immediate vicinity and an avoidance response similar to that occurring as a reaction to noise from work during the construction phase. However, it should be noted that there are currently no plans to use explosives during the decommissioning of the farm and during decommissioning there will be no driving of foundation piles, which is a major source of noise during the construction phase.

Noise and vibration generated during the decommissioning of the various elements of the farm can directly negatively affect ichthyofauna. These will be regional-scale, medium-term, reversible or irreversible, recurrent (during the construction period), medium-intensity impacts.

An assessment of the significance of this impact for the set of parameters of the Project constituting the 2015 NIS is presented in the table below.

The parameters of the Project approved by the Environmental Decision assume the construction of 40% fewer foundations than envisaged for the set of Project parameters constituting the 2015 NIS, so noise and vibration emissions during their decommissioning will be shorter. Thus, the 2015 Report considered that the variant indicated in the Environmental Decision would result in lower impacts on ichthyofauna than the 2015 NIS.

Therefore, it should be considered that the Project in the variant implemented after the requested change will cause even smaller impacts both with respect to the parameters of the Project approved by the Environmental Decision and from the set of parameters of the Project constituting the 2015 NIS.

Thus, it should be considered that both the nature of impacts and their extent and magnitude of impacts related to noise and vibration emissions will be the same as for the 2015 NIS and the variant approved by the Environmental Decision, and thus the update of the parameters for implementation and operation of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

Given that even in the 2015 NIS, noise and vibration impacts are negligible or small, **minimization measures are not required**.

Table 31. Assessment of the impact of noise and vibration on fish (decommissioning phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Cupcakes	Medium	High	legally protected species	Small (scale of exposure - regional, duration - medium-term, intensity - medium)	Small (magnitude of impact - low, importance of the resource - medium)
Dennik	Medium	High	legally protected species		
Cod	Large	High	commercial genre		Small (magnitude of impact - low, importance of the resource - high)
Plaice	Small	High	commercial genre		Negligible (magnitude of impact - low, importance of the resource - low)
Skarp	Medium	High	commercial genre		
Orchid	Medium	High	commercial genre		
Sprat	Medium	High	commercial genre		
Herring	Medium	High	commercial genre

9.3.4. Elimination of the "artificial reef"

Royal Haskoning DHV's technical report stipulates that wind turbine generators should be removed in their entirety, and foundations should be removed up to 3 meters below seabed level. The cables can be removed from the bottom or left covered under a layer of sediment. If erosion protection is used, it is not recommended to remove it. The remaining technical infrastructure should be removed.

During the construction phase, there is irreversible destruction of relatively small areas. In the case of decommissioning, an area similar in area is destroyed, but differing significantly in density and nature of settlement. At this stage, a significant part of the artificial reef is destroyed, providing habitat, feeding, shelter and reproduction sites for many representatives of ichthyofauna. This negative effect can be partially mitigated by, as proposed in the design study, leaving erosion protection on the bottom that is an important part of the habitat created during mining. The decommissioning of the OWF infrastructure will likely allow the area to resume fishing. This may cancel out the beneficial effect that the cessation of fishing activities has had on ichthyofauna, especially on the reproductive processes of some fish species (denfish, gobies).

The elimination of the "artificial reef" may directly negatively affect ichthyofauna (especially benthic and bottom spawning species). These will be local-scale, short-term, reversible or irreversible, repetitive (during the decommissioning period), medium-intensity impacts.

An assessment of the significance of this impact for the set of parameters of the Project constituting the 2015 NIS is presented in the table below.

In the case of the parameters of the Project after the amendment of the Environmental Decision, 50% fewer wind turbine foundations will be realized in relation to the parameters set by the Decision and as much as 70% less in relation to the set of parameters of the Project constituting the 2015 NIS. Thus, it should be recognized that the hard surface to be destroyed will be smaller than that which was considered at the stage of evaluation of the 2015 Report as well as for the variant indicated in the Environmental Decision. The project after the proposed modifications will have 70% fewer foundations compared to the set of parameters of the Project constituting the 2015 NIS, in addition, the possibility of using gravity foundations for the foundation of the power plant has been ruled out. Therefore, it should be considered that the Project scheduled for implementation after the amendment of the Environmental Decision, at the stage of its decommissioning, will cause even smaller impacts on ichthyofauna than the 2015 NIS. The smaller amount of hard substrate constituting the "artificial reef" that will be subject to decommissioning will result in less impact on ichthyofauna relative to that identified in the 2015 NIS.

Given that even in the 2015 NIS the impacts associated with the removal of the artificial reef on fish are negligible or small, **minimization measures** are **not required**.

Thus, it should be considered that both the nature of the impacts and their scope and magnitude are smaller than in the case of the variant approved by the Environmental Decision, and thus the updating of the parameters for the implementation and operation of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

Table 32. Assessment of fish impacts associated with habitat alteration due to seabed decommissioning activities (decommissioning phase, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Cupcakes	Medium	Low	legally protected species	Negligible (scale of exposure - local, duration - short term, intensity - medium)	Negligible (magnitude of impact - insignificant, importance of the resource - medium)
Dennik	Medium	Low	legally protected species		
Cod	Large	Low	commercial genre		Small (magnitude of impact - insignificant, importance of the resource - high)
Plaice	Small	Low	commercial genre		Negligible (magnitude of impact - insignificant, importance of the resource - low or medium)
Skarp	Medium	Low	commercial genre		
Orchid	Medium	Low	commercial genre		

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Sprat	Medium	Low	commercial genre		
Herring	Medium	Low	commercial genre

9.3.5. Cumulative impact

At the liquidation stage, the accumulation scenario is the most difficult to predict. In the most far-reaching one, all wind farms built are decommissioned at the same time (i.e. depending on the scenario and obtaining additional connection conditions), e.g. as a result of legal changes that make their operation completely unprofitable.

The magnitude of the cumulative impact of the decommissioning phase can be considered like the construction phase in two ways, understood as the dependence of the impacts associated with the decommissioning of the wind farm itself and the cumulative impacts as a result of the demolition of various other installations, and in this case listed in Section 3.2.

In the first case, the total scale of impact of the BIII offshore wind farm is influenced by the intensity of the factor and the timing and scale of the impact. For the most part, the magnitude of the impact was described as insignificant and the significance of the impact as low or negligible. Taking into account the specified order of decommissioning of the construction of individual elements estimated at 3 years, the demolition can be classified (according to the methodology) as: **negative in nature, direct impact, local scale, impact frequency constant, medium duration, medium intensity.**

Taking into account the Impact Significance Assessment Matrix, the impact of decommissioning the OWF will be a small impact for cod and negligible for other species.

In the second case, assuming that the impact of the other farms is identical to that of OWF BIII, and that they will be decommissioned at the same time, the scale of impact may increase to a regional level. Then (also taking into account the Impact Significance Assessment Matrix) the cumulative impact of all investments will be classified as low.

It should be emphasized here that due to the reduction in the number of wind power plants planned for the Project, the cumulative impacts will also be correspondingly smaller if all the OWFs are decommissioned.

In addition, a possible reduction in cumulative impact will occur as a result of the reduction in the time of the work scheduled for decommissioning and the involvement of fewer resources to do so.

In order for significant impacts to occur, it would be necessary for a factor to have an impact on a scale larger than regional, having a long-term impact with high frequency.

10. Related impacts

The primary element of **receptor-associated** interactions may be **trophic relationships between benthos and fish.** Habitat change during construction will lead to the complete destruction of the benthos in the

areas of excavation for foundations and trenches where cables will be run. This will deplete food resources for benthic fish. However, the area where the habitat change will completely eliminate benthic organisms will be relatively small (about 0.4% of the total project area in the variant after the amendment of the Environmental Decision). Also, the reduction in the food base of fish caused by the negative impact of covering the bottom with a layer of fine sediment settling from the water depths should not be significant. The results of studies of the structure of the zoobenthos and analyses of its susceptibility to the influence of the above-mentioned factor presented in the expert analysis of the benthos (Studies of the benthos in the area of the OWF Baltic Central II. Final Report with Environmental Impact Assessment) indicate that organisms, which are a component of the diet of bentophagous fish, such as bivalves or crustaceans (Monitoring of ichthyofauna of the area of the OWF Central Baltic III. Final Report with Study Results - Volume III Section 7 of the report) are not sensitive to the impact of increased sedimentation. Thus, there is no reason to assume that this factor can negatively affect ichthyofauna by reducing the availability of food for benthic fish.

Inhabitation of turbine structural elements by benthic epiphytic organisms increases the potential food base for benthic fish. As predicted in the benthic survey report, the dominant component of the epiphytic fauna will be the mussel*(Mytilus trossulus*), which is an important food component for flounder and plaice. Thus, while a large increase in the biomass of *M. trossulus* may result in an increase in the abundance/biomass of flat fish in the BIII OWF area, a marked increase in the abundance of other species is not expected. Such a conclusion is confirmed by studies in the area of the Nysted OWF (Danish Straits), where no changes were observed in the distribution of ichthyofauna associated with the location of the turbines. This may have been due to the very homogeneous taxonomic structure of the benthic fauna that populated the structural elements. The newly formed hard substrate was dominated entirely by mussels*(M. edulis*), which are not an important food component of the ichthyofauna in the area, hence no fish were observed to congregate near the turbines.

The appearance of new habitats dominated by epiphytic organisms can create suitable additional substrate for demersal fish eggs (herring, gobies, demersal, horse mackerel, devil hens) as well as provide hiding places for early life stages of fish, thus positively affecting spawning efficiency and fry survival.

Another factor indirectly related to habitat change and affecting fish is, in the furthest scenario, the exclusion of the OWF area from fishing activities. This can positively affect ichthyofauna by eliminating fishing mortality and disruption of reproductive processes locally.

Possible losses to fisheries caused by the ban on fishing in the OWF area are not expected to be large due to the aforementioned low fishing productivity of the area and the possibility of increased fishing productivity in neighboring areas.

The destruction at the OWF decommissioning stage of part of this habitat created by benthic organisms, as well as the return to fishing activities after the technical infrastructure is removed, is likely to have a negative impact on the diversity and abundance of ichthyofauna on a local scale.

11. Unplanned impacts

Unplanned impacts are the result of sudden events or failures that are not related to activities included in the project schedule (e.g., leakage of toxic substances into the water due to a collision between two vessels).

In assessing the significance of unplanned impacts, additional factors were taken into account, i.e. the probability of an event that will be the source of the impact and its potential consequences.

Based on data from other OWF projects and from similar projects, as well as on the knowledge and experience of the study's authors, the following potential unplanned events that could become a source of unplanned environmental impacts of offshore wind farms were selected:

- leakage of petroleum substances during normal operation or in an emergency situation (collision, accident or construction disaster),
- accidental release of municipal waste or domestic sewage,
- accidental release of construction materials or chemicals,
- contamination of the water tone and bottom sediments with antifouling agents;
- noise emissions associated with unexploded conventional weapons explosions.

It should be noted that as a result of unplanned events , the abiotic environment, primarily marine waters and, to a lesser extent, bottom sediments, may be directly contaminated. On the other hand, indirectly, these events can also affect living organisms that inhabit or otherwise use the seabed, the water table and the sea surface.

Compared to the 2015 Report, this Report has been supplemented with impacts related to noise emissions associated with explosions of unexploded conventional weapons. Since the 2015 Report, knowledge of both unexploded POM conventional weapons and the potential impacts associated with their disposal has increased.

A full description of potential unplanned events can be found in Section 12 of Volume II of the report. In contrast, the indirect impacts of unplanned events on fish are assessed below, based on this description .

11.1. Pollution of water depths and bottom sediments with petroleum substances (during normal ship operations)

During normal ship operation, spills of various types of petroleum substances (lubricating and diesel oils, gasoline) can occur. They will be a minor contributor to the deterioration of water quality. Heavier oil fractions can be sorbed on the surface of organic and mineral suspensions, which will cause their specific gravity to increase and gradually sink to the bottom. There they can be bound by bottom sediments. However, due to the nature of the sediments in the BIII offshore wind farm area (small amount of organic matter and low content of fine fractions), they will not cause any noticeable deterioration in their quality. It should be assumed that these spills will be small (stage I), up to 20^{m3}.

Visible traces of such contamination under favorable conditions can disappear spontaneously due to evaporation and dispersion in the water. The size of these spills will be practically limited to the OWF area.

As a primary minimization measure, it is recommended that vessels be supplied with means to deal with minor oil spills. Mitigation activities are described in more detail in Section 12 of Volume II of the EIA.

The spill of a small amount of petroleum substances into the sea may indirectly negatively affect ichthyofauna. These will be local, temporary or short-term, reversible, repeatable, low-intensity impacts. Experimental studies have shown that different taxonomic units of animals have very different resistance to pollution by petroleum compounds. The lower limit of impact on fish is estimated at 16 $^{mg/dm3}$, while juveniles react much more strongly and an oil concentration of 1.2 $^{mg/dm3}$ is taken as the limit for them. However, it should be noted that even at a concentration of 0.05 $^{mg/dm3}$, fish meat can have an unpleasant odor, which eliminates it from the trade (Fabisiak, 2008).

An assessment of their importance to fish, if the set of parameters of the Project constituting the 2015 NIS is implemented, is presented in the table below.

In the variant assumed to be implemented by the Environmental Decision, 40% fewer power plants were to be built, respectively, than envisaged for the set of parameters of the Project constituting the 2015 NIS, which also entails the use of fewer vessels for the implementation of the project, its operation or decommissioning. Thus, the risk of occurrence and the number of potential leaks will decrease proportionally. Thus, it is considered that the variant indicated for implementation in the Environmental Decision will result in lower impacts on ichthyofauna than the 2015 NIS.

With the above in mind, it should be pointed out that the Project after the update will have 70% fewer wind turbines than the set of Project parameters constituting the 2015 NIS and 50% fewer than the variant envisioned in the Environmental Decision, which means that the risk of generation and the number of potential spills will be even lower than the variant indicated in the Environmental Decision.

Table 33. Assessment of the impact on fish of a small amount of petroleum substances released into the sea during normal vessel operations (any stage, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Cupcakes	Medium	Low	During the normal operation of ships, a small leakage of petroleum substances may occur.	Insignificant (scale of exposure - local, duration - temporary or short-term, intensity - low)	Negligible (magnitude of impact - insignificant, importance of the resource - medium)
Dennik	Medium				Negligible (magnitude of impact - insignificant, importance of the resource - medium)

11.2. Pollution of the water tone and bottom sediments with petroleum substances (in an emergency)

During the construction, operation or decommissioning of the farm, leakage of substances may occur as a result of a shipwreck or collision, a construction disaster of one of the farm facilities, as well as during maintenance work. In the event of a ship collision or collision, a Grade III spill can be expected, i.e. more than 50^{m3}, but a maximum of about 200^{m3} (cf: Unplanned Events, Section 12 of Volume II of the EIA).

It has been calculated that the probability of serious accidents is very low, on the order of $^{10-5}$ - $^{10-4}$. For the Southeast Baltic, which may include the BIII offshore wind farm area, the risk of collision was estimated at 1 case per 1060 years. The significance of this impact can be considered negligible, as the unplanned impacts described are extremely rare and practically impossible. In this case, there are organizational structures, plans of conduct in carrying out actions to combat hazards and pollution, and effective methods of cleaning up pollution.

However, if an oil spill were to occur in the area of OWF BIII during its construction, 24 hours after the accident at a probable wind direction distribution for the Southern Baltic of 3°B, its extent would cover the eastern slope of Slupsk Shoal (Pawelec et al., 2014), threatening not only the benthic organisms of the farm area, but the Slupsk Shoal Natura 2000 area, which protects, among other things, the habitat of marine clam beds and many species of macroalgae. In the best-case scenario (calm sea), oil splashes will not threaten the benthos, but only those groups of organisms living in the water's depths. During a storm, the dispersion of the oil spill will contaminate the food chain in the area of the failure (Malaczynski and Czarnecki, 2010). Oil spilled at sea is subject to a number of physical and chemical processes, the intensity of which depends on the type of oil, as well as environmental conditions. Among the most significant are: dissolution in water, mainly light hydrocarbons, evaporation of low-boiling fractions, dispersion in seawater, adsorption on suspension, sedimentation of heavy fractions, oxidation and microbial degradation (Burwood and Spears, 1974). The solubility of hydrocarbons in water and some non-polar compounds included in oils is low. There has also been a recent increase in deliberate oil pollution. Water discharged from ships overboard usually contains more than 15 $^{mg/dm3}$ of compounds. These are usually small volumes, less than 1^{m3}, and therefore difficult to detect (Fabisiak, 2008). In addition to direct toxic effects on ichthyofauna in the event of a large accident, oil spills cause indirect effects by upsetting gas relations in the aquatic environment, resulting in oxygen loss in the bottom zone and the occurrence of dead zones. It should be noted that the threshold oxygen value for fish is 2 mg/L. Experimental studies have shown that different taxonomic units of animals have very different resistance to pollution by petroleum compounds. The lower limit of impact on fish is estimated at 16 $^{mg/dm3}$, while juveniles react much more strongly and an oil concentration of 1.2 $^{mg/dm3}$ is taken as the limit for them. However, it should be noted that even at a concentration of 0.05 $^{mg/dm3}$, fish meat can have an unpleasant odor, which eliminates it from the trade (Fabisiak, 2008).

The spill of more petroleum substances into the sea may indirectly negatively affect ichthyofauna. These will be local, short-term, reversible, repetitive, low-intensity impacts.

An assessment of their importance to fish, if the set of parameters of the Project constituting the 2015 NIS is implemented, is presented in the table below.

In the 2015 Report, for the parameters of the Project approved by the Environmental Decision, it was assumed that 40% fewer power plants would be built than envisaged for the set of Project parameters constituting the 2015 NIS, which also entails the use of fewer vessels for project implementation, operation or decommissioning. Thus, the risk of occurrence and the number of potential leaks will decrease proportionally. Thus, it is considered that the variant that was indicated for implementation in the Environmental Decision will cause lesser impacts on ichthyofauna than the 2015 NIS.

With the above in mind, it should be pointed out that the Projects in the parameters after the update will have 70% fewer wind turbines than in the 2015 NIS and 50% fewer than in the **variant approved by the Environmental Decision,** which means that the risk of generation and the number of potential spills will be even lower.

Thus, it should be considered that both the nature of the impacts and their scope and magnitude are smaller than in the case of the variant approved by the Environmental Decision, and thus the updating of the project parameters does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

Table 34. Assessing the impact on fish of more petroleum substances released into the sea during an accident or collision (unplanned impacts, any stage, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact

11.3. Contamination of water bodies and bottom sediments with accidentally released municipal waste or domestic sewage

During the construction of the wind farm, waste, municipal and other, not directly related to the construction process, as well as domestic sewage, will be generated on vessels as well as at the

construction facilities located on land (at the port serving the project). Their expected types of quantities, as well as how they will be handled, are presented in Section 10 of Volume II of the EIA. Waste and wastewater can be accidentally released into the sea when picked up from ships by another vessel (only in random cases, related to adverse weather or transfers between vessels) and in the event of an accident, causing a local increase in nutrient concentrations and deterioration of water quality and sediment, and indirectly negatively affecting fish. However, the pollutants should quickly disperse, so they will not contribute to permanent deterioration of the environment in the project area. It is recommended to create internal procedures to regulate the handling of waste and wastewater.

-

An assessment of their importance to fish, if the set of parameters of the Project constituting the 2015 NIS is implemented, is presented in the table below.

The variant that was considered in the 2015 Report and approved by the Environmental Decision assumes the construction of 40% fewer power plants than envisaged in the set of parameters for the Project constituting the 2015 NIS, which also entails the use of fewer vessels for project implementation, operation or decommissioning. Thus, the risk of accidental release of municipal waste or domestic sewage into the water will be reduced proportionately.

With the above in mind, it should be pointed out that in the case of the Project, after the proposed modifications to the conditions of implementation and operation specified in the Environmental Decision, there will be 70% fewer wind turbines than in the case of the 2015 NIS and 50% fewer than in the **variant approved by the Environmental Decision,** which is equivalent to the fact that the risk of generation and the number of potential spills of municipal or domestic wastewater will be even lower than in the case of the variant indicated in the Environmental Decision.

Thus, it should be considered that both the nature of the impacts and their scope and magnitude are smaller than in the case of the variant approved by the Environmental Decision, and thus the updating of the Project parameters does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

Table 35. Assessing the impact on fish of more petroleum substances released into the sea during an accident or collision (unplanned impacts, any stage, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Cupcakes	Medium	Low	During the construction, operation or decommissioning of the farm, a small amount of municipal waste or domestic sewage may be accidentally released into the sea. 11.4. Contamination of water bodies and bottom sediments with accidentally released chemicals and waste from construction, operation or decommissioning of the farm

During the construction of the wind farm, waste directly related to the construction process will be generated on vessels, at construction facilities located onshore (at the port serving the project) and at the project site. These can include damaged parts of the farm's assembled components, cement, grout, mortar, binders used to join the foundation and power plant components, and other chemicals used during construction work. They can be accidentally released into the sea.

The bulk cement is packed in bags of about 1^{m3}. It was assumed that incidents involving the sinking of about $5^{m3\ of}$ product could occur during handling. Grouts, mortars and other binders often contain hazardous substances. E.g., epoxy (two-component) grouts contain in various proportions: epoxy resin, alkyl glycidyl ethers, polyamines. Once they enter the water depths, due to their high density of about 1.3 $^{g\text{-}cm\text{-}1}$, they sink and are deposited on the bottom. These substances are considered a serious threat because they cannot be easily removed from the bottom and are toxic to marine organisms.

During the operation of the farm, maintenance of its facilities will be carried out. Accidental release of small amounts of waste or operating fluids into the sea cannot be ruled out.

During decommissioning of the farm, it seems inevitable that bottom sediments will be contaminated with waste from the process. The magnitude of this impact will depend on the method adopted for carrying out this work (cf: description of the decommissioning stage - Volume II Section 6 of the report), and the greatest pollution may occur if the gravity foundations have to be crushed.

Each of these impacts can negatively affect fish.

This type of pollution affects the ichthyofauna causing neurophysiological and behavioral changes, as well as affecting reproduction. These effects can often be interrelated: neurological changes can affect behavior, changes in behavior can affect reproduction, and so on.

Compounds like resins, esters and binder fragments do not always have an effect on the target organism or communities. This depends on the concentration of the substance and the time of exposure. These effects can be acute or chronic. Acute toxicity occurs quickly, is often fatal and rarely reversible. Chronic ones develop after prolonged exposure to low doses and can eventually lead to death. In the case of a wind farm, this will not happen, as a detailed plan is generally developed to deal with risks and pollution arising during the construction, operation and decommissioning of the OWF, which develops

minimization measures and how to deal with such events. **By analogy, the 2015 Report recommends creating such procedures for the BIII OWF project.**

The anticipated types and quantities of waste are presented in Section 10 of Volume II of the EIA.

The release of chemicals and waste from the construction, operation or decommissioning of the farm into the sea may indirectly negatively affect ichthyofauna. These will be local, short-term, reversible or irreversible, repetitive, low-intensity impacts.

An assessment of their importance for fish, in the case of implementation of the set of parameters of the Project constituting the NIS 2015, which is shown in the table below.

In the 2015 Report, for the Project parameters approved by the Environmental Decision, it was assumed that 40% fewer power plants would be built than envisioned for the set of Project parameters constituting the 2015 NIS. Thus, the risk of releasing chemicals and waste from the construction, operation or decommissioning of the farm into the sea will be reduced proportionately. Thus, it is considered that the variant indicated for implementation in the Environmental Decision will result in lower impacts on ichthyofauna than the 2015 NIS.

With the above in mind, it should be pointed out that the Project in the updated parameters will have 70% fewer wind turbines than in the 2015 NIS and 50% fewer than in the variant approved by the Environmental Decision, which means that the risk of creation and number of potential releases to the sea of chemicals and waste from the construction, operation or decommissioning of the farm will be even lower than in the variant indicated in the Environmental Decision.

Thus, it should be considered that both the nature of the impacts and their scope and magnitude are smaller than in the case of the variant approved by the Environmental Decision, and thus the updating of the conditions for implementation and operation of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

Table 36. Assessment of the impact on fish of chemicals and wastes from the construction, operation or decommissioning of the farm released accidentally into the sea (unplanned impacts, any stage, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Cupcakes	Medium	Low	During the construction, operation or decommissioning of the farm, there may be accidental release of related wastes into the sea, and at any stage of the project there may be accidental release of various types of chemicals.	Negligible (scale of exposure - local, duration - short-term, intensity - low)	Negligible (magnitude of impact - insignificant, importance of the resource - medium)
Dennik	Medium				Negligible (magnitude of impact - insignificant, importance of the resource - medium)

11.5. Contamination of water depths and bottom sediments with antifouling agents

To protect the hulls of ships from overgrowth, biocides are used, which may include, for example, copper compounds, mercury compounds, organotin compounds (such as tributyltin - TBT). These substances can pass into the water's depths and eventually be retained in the sediment. It should be assumed that the emission of these compounds will be limited by dilution in the water depths. Of the substances listed, organotin compounds are the most harmful (toxic) to aquatic organisms. TBT (the most harmful substance) is currently banned in antifouling paints, but the presence of these compounds in older units cannot be ruled out. **It is recommended that vessels whose hulls have not been coated with TBT-containing antifouling paint be used at any stage of the project. This will eliminate this most harmful impact on aquatic organisms.**

TBT has been detected in the tissues of fish living in the marine environment of the Baltic Sea and is at an acceptable level as far as human health is concerned. TBT threatens the marine environment and, above all, organisms at a lower level of the trophic network, such as the fauna inhabiting bottom sediments. Tributyltin compounds are moderately to highly persistent organic pollutants that undergo bioconcentration in the food chain of marine predators. They are harmful to many aquatic organisms, including algae, mollusks and crustaceans, fish. (Toropovs, 2012)

Studies have shown the effects of TBT on embryonic development (skeletal deformities, abnormalities in the development of internal organs). TBT has a detrimental effect on the immune system, reducing resistance to infection in fish that live on the sea floor. They are exposed to high concentrations of TBT because relatively high levels of TBT are found in muddy sediment (Antizar-Ladislao B., 2008).

Antifouling agents can indirectly negatively affect ichthyofauna. These will be local, temporary or short-term, reversible, repeatable, low-intensity impacts.

An assessment of their importance to fish, if the set of parameters of the Project constituting the 2015 NIS is implemented, is presented in the table below.

The Project variant approved by the Environmental Decision stipulates that 40% fewer power plants will be built than envisioned in the 2015 NIS. This circumstance will therefore affect the number of hull units by reducing the risk of releasing antifouling substances.

With the above in mind, it should be pointed out that the Project in the updated parameters will generate 70% fewer wind turbines than in the 2015 NIS and 50% fewer than in the variant indicated in

the Environmental Decision. Therefore, it should be considered that the risk of antifouling releases for the Project implemented after the amendment of the Environmental Decision is lower than assumed when it was issued.

Thus, it should be considered that both the nature of the impacts and their scope and magnitude are smaller than in the case of the variant approved by the Environmental Decision, and thus the updating of the parameters for the implementation and operation of the Project does not affect the outcome of the environmental impact assessment conducted as part of the proceedings during which the Environmental Decision was obtained.

Table 37. Assessment of the impact on fish of antifouling agents released into the sea (unplanned impacts, any stage, NIS 2015)

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact
Cupcakes	Medium	Low	During the normal operation of ships, the release of antifouling substances from their hulls may occur.	Insignificant (scale of exposure - local, duration - temporary or short-term, intensity - low)	Negligible (magnitude of impact - insignificant, importance of the resource - medium)
Dennik	Medium				Negligible (magnitude of impact - insignificant, importance of the resource - medium)

11.6. Impacts associated with noise emissions during UXO unexploded ordnance

If the elimination of UXOs through their in situ detonation proves necessary, such activity could affect fish at the individual level. This is because the detonation of conventional weapons residues will be a

source of underwater noise and vibration emissions. The handling of UXO and the likelihood of such an event are described in more detail in Volume II Section 12 of the Report.

The scale and scope of impacts associated with a possible detonation on fish will vary with the size of the detonated cargo, but will not exceed the regional scale. These will be high-intensity but temporary impacts. The effect of noise emissions during detonation can, in extreme cases, cause bodily harm, including fatal injuries, to fish that would be in the immediate vicinity of the explosion site (at a distance of 600-700 m, see: Table 38below). The maximum zones of potential impact in the form of fatal injuries and physical injuries to fish resulting from noise emissions associated with controlled detonation of unexploded ordnance are presented in the table below.

Table 38. Limit distances from the source of the UXO explosion relative to the threshold values of fish sensitivity to underwater noise impacts

Detonation of unexploded ordnance	Threshold value	150 kg TNT		950 kg TNT	
		Summer	Winter	Summer	Winter
Impact on fish	SEL (Cum*) [dB re $^{1\mu Pa2s}$]	[km]	[km]	[km]	[km]
Mortality (fatal injuries)	207 dB (229-234 dB peak.)	0.6	0.6	0.7	0.7
Physical injuries	203 dB	0.7	0.7	0.7	0.7

Source: SMDI/Ramboll 2019

An assessment of the impact of UXO detonation noise on fish on an individual basis is presented in the table below.

Table 39. UXO explosions - analysis of the significance of the impact on fish at the individual level

Receptor	Importance of the resource	Vulnerability to impact	Rationale for impact assessment	Magnitude of impact	The significance of the impact

Source: SMDI/Ramboll 2019

Although the impact of UXO detonation on fish in the form of permanent injury and/or mortality will not be an impact that is considered significant, both in terms of individuals and in terms of their populations in the area of OWF BIII, due to the irreversibility of its effects, it is recommended to implement a minimization measure in the form of conducting a sonar survey of the area of potential detonation, allowing to determine the presence of schools or groups of fish in the area. Based on the results of the sonar survey, an assessment should be made as to whether the timing of munitions clearance is appropriate or whether detonation should be postponed. This action is aimed at protecting schools of fish that may be in the area of OWF BIII.

11.7. Cumulative impact in emergency situations

The only unplanned impact that may be cumulative will be potential oil spills resulting from a disaster or collision.

In the case of simultaneous implementation or operation of several projects, vessel traffic in neighboring areas also increases, with an increased risk of such an event. To the north of the farm is a heavily used shipping route, in the area of which there is an increased risk of oil spills. There are also three hydrocarbon exploration and appraisal licenses in the area. During exploration and in the event that potential deposits of the aforementioned raw materials are discovered and a decision is made on their possible extraction in the region, vessel traffic may increase.

The spill of more petroleum substances into the sea may indirectly negatively affect ichthyofauna. These will be local, short-term, reversible, repetitive, low-intensity impacts.

An assessment of their importance to fish, for the set of parameters of the Project constituting the 2015 NIS is presented in the table below. It should be noted here that the parameters of the Project after the amendment of the Environmental Decision will be significantly lower than the 2015 NIS.

The variant approved by the Environmental Decision assumes that 40% fewer power plants will be built than envisaged for the set of parameters of the Project constituting the 2015 NIS, which also entails the use of fewer vessels, as well as the shorter operating time required for the project, its operation or decommissioning. Thus, the risk of occurrence and the number of potential leaks were reduced proportionally. At that time, it was considered that the variant identified for implementation in the Environmental Decision would result in lower impacts on ichthyofauna than the 2015 NIS.

With the above in mind, it should be pointed out that the Project in the updated parameters will have 70% fewer wind turbines than the set of parameters of the Project constituting the 2015 NIS and 50%

fewer than the **variant approved by the Environmental Decision,** which means that cumulative impacts will be lower.
